MASTURBATION.

A Clinical Lecture.

BY LAWSON TAIT, M.D., F.R.C.S.,
HONORARY PROFESSOR OF GYNECOLOGY, QUEEN'S COLLEGE, BIRMINGHAM.

THIS painful subject is usually involved in such mystery, and spoken of so seldom and so incompletely by medical authorities, that it is by no means easy to determine to what extent it prevails, how to discriminate its victims or how to suggest a remedy. When discovered in a school, or in a family, it strikes everybody with such horror that it is at once concealed and hushed up, instead of being treated, as it always ought to be, as a disease; and the unfortunate children who are discovered in the practice are regarded by their discoverers as having sunk to the lowest moral depths.

It is a sad misfortune that all sexual questions are so completely hidden from children at puberty that they are driven to make discoveries for themselves, often with disastrous results. One of the greatest practical results of the discovery of Mr. Darwin of the descent of man from the animals which have gone before him is that by it the sexual instincts, or, as they are generally and most unfortunately termed, the sexual passions, are shown to be the most necessary, as well as the most prevalent of all the instincts which have been evolved by the necessities of animal existence. We might just as reasonably speak of the respiratory passion or the circulatory passion. Respiration and the circulation of the blood are essential to animal existence. As those with the best breathing, and those with the best blood circulation necessarily have, under certain circumstances, the best chance of survival in the struggle, so do those with the best capacity for procreation serve their purpose in the struggle for the maintenance of the race, of the species, of the great chain of life itself. All the most pronounced organs adapted for struggle are directed toward sexual success. The sexual instinct has thus become everywhere in the scheme of creation the great weapon of evolution. That it should be curbed, properly restrained and judiciously directed is now one of the great objects of civilization—an object to be aided in every good and wholesome way. But I doubt very much if some of the methods employed for this purpose are judicious.

The female organism has always been merely the vehicle for the maturation of the ovum, and for the receptacle of the fertilizing influence of the male; being, in fact, what we may call the passive factor in the reproductive act. For her part of the process, then, only enough of sexual passion or instinct is required to indicate to the male the stage at which his share may be effectually performed. For the male, on the contrary, a constant tendency to aggression is necessary, that he may be in readiness at the time required.

Further, the struggle for the survival of the fittest has constantly been carried out in its chiefest severity amongst the males of all animals, and only partially amongst the females; so that it has come to be that the physically fittest has necessarily been also the sexually most powerful. This requires no proof, for it is demonstrated by the enormous prices given by breeders of all animals for the best males compared with the prices obtained for the best females. In fact, through countless generations of all animals, the sexual instinct, above all others, has been developed in the males by the constant elimination of the least fit, and the subsequent success of the sexually fittest. Every provision of weapon, offensive or defensive, from the spur of the cock to the tooth of the tiger, has its primary object in enabling its possessor to compete successfully in the sexual struggle. Even in civilized life, the chief desire to possess wealth seems to be to make a good marriage, and the daughters of our race walk off with the most successful (that is, the wealthiest) suitors, much as the tigress walks off with the victorious male. It ought to be, therefore, no matter of surprise that in the human race the sexual instinct is very powerful in man, and comparatively weak in woman.

Another matter must here be also noticed. The females of all animals resist the advances of immature males for the reason that the struggles of the fittest has taught the races that the offspring of such advances are less fit for survival than the offspring of the mature male. Any one who has kept poultry must have noticed how soon cockerels make advances to hens, and how persistently the latter refuse them, and how they punish the cockerels for the attempts until their perfect maturity has been attained. Considering these two great facts in animal life, it is not surprising, then, that masturbation is very common among boys and comparatively rare among girls. Indeed, if we are to believe some authors, and I must say I am inclined so to do, boys always discover the practice for themselves, and very few of them are free from it. I am quite certain, on the other hand, that it is relatively rare amongst girls, and that it is generally the result of direct contamination. Sometimes, however, they discover it, for I have met with two instances of children, almost infants, one being only four years of age and the other six, where it was absolutely impossible that it could have been communicated to them, and in both of whom it was found to be utterly impossible to check it. They were both of defective intellects, a condition which I regarded as the cause of the masturbation rather than, as might be more generally held, that the vice was the cause of the deficiency. I look upon it, in fact, as a reversal of moral type, for no one can ever have watched the habits of monkeys without having discovered that masturbation is almost universal among them in confinement. Whether it may be practised by them in their native woods is not yet known, but I fancy that it is rather the result of their luxurious life, their

freedom from the strain of earning an honest livelihood in the native circumstances of their wild life. Idleness and luxury are always provocative of lust in monkeys as in men.

Between the period of puberty and the time when young members of the human race may legitimately follow out their instinctive tendencies, there are a number of years during which the male glands are active and troublesome, and the males discover a method of relief. No such relief is wanted for the female glands, for they discharge their products without it. But if the rudimentary instinct be once directed into this artificial element, it is often carried to great excess, and there can be no doubt that much mischief is sometimes done to the economy. The most pernicious effects are met with when the contamination reaches a congregation of young women, as in a girls' school. I have been consulted concerning epidemics of this kind, both in boys' and girls' schools, and have always found the chief difficulty to be that of persuading those having charge of the schools that the practice was a physical delinquency rather than a moral evil, and that the best remedy was not to tell the poor children that they were damning their souls, but to tell them that they might seriously hurt their bodies, and to explain to them the nature and purport of the functions they were abusing. In one instance, the head of a very large girls' school took my advice on this subject, with the best results.

The evil effects of masturbation have been greatly overrated, thanks to a reticence on the part of those who know all about it, and this has permitted a disagreeable subject to fall into the hands of those who live by trading on the ignorance and misfortunes of their fellow-beings. In the case of men, it may, and often does, result in serious mischief, especially to those of weakly constitution. In women, I believe, it is not often carried to such an extreme as to do any harm, though I have met with cases in which serious injury has resulted; and I am quite certain that girls may almost always be induced to give up the practice, when a reasonable explanation is afforded to them of the risks attached to it. I have had under my care a lady, who was educated in a convent in Belgium, where, according to her statement, the practice was prevalent, and where she was initiated into it at fourteen years of age. She voluntarily informed me that she has continued it ever since, though she has married and borne several children. She is now nearly forty years of age, and enjoys robust health.

But there is another class of cases well illustrated by two patients whom I have watched for some years. They are both slightly built, and rather delicate blondes. They were both corrupted at school early in life. In one of them, an immoderate indulgence at a menstrual period brought on an hæmatocele, which has ever since been a source of ill health, and has rendered her married life infertile. In the other, a similar excess soon after marriage induced a miscarriage, a repetition of her indulgence excited an hæmatocele with perimetritis, and to the same cause, I am sorry to say, we are obliged to attribute recurrent inflammatory attacks, which render her a chronic invalid. In neither of these cases has advice been of the slightest use, even though couched in terms of the strongest kind; but I am bound to say that such a disappointing result is very unusual.

The method of practising the vice is usually by the finger, but devices of a still more mischievous character have come under my notice. In young children, masturbation is often associated with defective mental development, and it should always be a ground for placing them under special care. In all establishments where the young of either sex are congregated the system of separated cubicles should be employed; and children ought never to be allowed, under any circumstances whatever, to sleep with servants. In every instance where I have known a number of children to be affected, the contagion has been traced to a servant.

I think it possible that, in some inveterate cases, clitoridectomy might be beneficial, but I have never tried it save in one instance. It is certainly the case, as I have elsewhere said, that the chief point of local excitement in the sexual act is in the clitoris, and a recognition of this fact involves a very strange and most discreditable piece of surgical history.

Some thirty years ago, there lived and flourished in London a surgeon of great ability, Mr. Baker Brown, whose influence in the history of ovariotomy will be displayed in its appropriate place. Mr. Baker Brown was not a very accurate observer, nor a logical reasoner. He found that a number of semi-demented epileptics were habitual masturbators, and that the masturbation was, in women, chiefly effected by excitement of the mucous membrane on and around the clitoris. Jumping over two grave omissions in the syllogism, and putting the cart altogether before the horse, he arrived at the conclusion that removal of the clitoris would stop the pernicious habit, and therefore cure the epilepsy. He operated in an enormous number of cases, for epilepsy is very common, and patients and their guardians will submit to almost anything which promises a hope of relief. There can be no doubt that many cases were temporarily benefited, just as cases of epilepsy are benefited for a while by castration (in the male), removal of the uterine appendages (in women), and trephining (in both sexes). Besides, Mr. Baker Brown's operations had no mortality, and the reduction of the sexual distemper of a number of epileptics, even for a while, or to some extent, was of itself a benefit. But Mr. Brown carried his efforts to a most injudicious extent, due to the fact that he was suffering from very extensive cerebral softening, and really was incapable of forming a sound judgment. His subsequent illness and death proved this, and I have a large amount of documentary evidence in my possession, which some day will see the light, which will place the terrible story of this most unfortunate man in a light altogether different from that in which it has hitherto been regarded.

As a result of the disease from which he suffered, he resisted the advices of his colleagues and the committee of his hospital, and he ran his hobby till he got into trouble with the Commissioners of Lunacy for a technical infringement of the conditions under which lunatics may be detained in places not licensed for their reception. This would have been of little consequence had he not been a successful ovariotomist, and had he not been pursued by a rival as relentless as he was cruel and persevering. The authorities of the Obstetrical Society were induced to take up the matter, and Mr. Baker Brown was expelled from the Society, a large part of the evidence against him being furnished from the common-

place book of a rival who seemed to have been dogging his steps for years.

Calmly regarded now, after the lapse of twenty years, Mr. Baker Brown's ruin is a matter of regret. The voices of his colleagues, who knew the diseased condition of his brain, ought to have had greater weight with his professional judges, and milder measures ought to have been adopted, measures less likely to bring scandal and discredit on the profession to which Mr. Baker Brown was a distinguished ornament. This, I predict, will be the judgment of another generation, when all the actors in the drama are gone from amongst us.

One disastrous result came from the decision of the Obstetrical Society at once, as might have been expected. The operation of clitoridectomy as a means of mitigating a depraved sexual appetite was absolutely discarded, and I have never heard a surgeon say he had performed it since 1867. Yet I am certain that in many cases it would be useful. I have performed it once, in a case where it was suggested by Dr. Thursfield, of Bridgworth, for reasons altogether too disgusting for publication. The following letter from Dr. Thursfield, two years after the operation, completely justifies his suggestion and my carrying it out:

"You will remember I told you, a few months after the operation, that she was dreadfully depressed in spirits and annoyed that she had submitted to it; soon afterward she became better in health and strength, and now, I am glad to say, she is improved morally and physically.

"She is nurse, companion and governess to her sister's children; and when I saw her, a month back, at first I did not recognize her, she was so bright and cheerful in manner and appearance; my opinion of her case is, that the operation has saved her from suicide or the asylum, and I believe she will be, instead of an encumbrance and anxiety to her friends, a comfort and help."

TWO CASES OF GLOSSY SKIN, WITH CAUSALGIA FOLLOWING INJURY OF THE NERVES.

By THOMAS D. DUNN, M.D.,
of West Chester, Pa.

Case I.—Mrs. H., aged seventy-nine, fell on the 9th of July, 1887, and sustained a fracture of the neck of the left thigh. By great effort, after the accident, she succeeded in dragging herself to the second story and into bed. It was twenty-four hours before I was summoned. During that period she suffered intense pain, but thought the injury nothing more than a sprain which would soon improve with rest. There was considerable swelling around the hip-joint, and about two inches of shortening. The reduction of the fracture was easy and afforded the patient immediate relief. The dressing consisted of the ordinary extension by a weight attached to adhesive straps applied to either side of the leg below the knee and held by a roller bandage; counter-extension by elevating the foot of the bed, and lateral support by a short sand-bag to the inner side of the leg and thigh, and a long one extending from the foot to the axilla.

For a few days the limb was comfortable, but the patient suffered greatly from her back, and fearing bedsores might complicate matters, the Nathan R. Smith apparatus was substituted to enable her, by swinging the limb, to move about the bed. This induced so much suffering of the foot and thigh that the former dressing was re-applied.

About four weeks after the injury she began to complain of pain below the knee, which was greatest over the dorsum of the foot. This gradually became worse, and in two weeks was so severe that the extension apparatus was removed. She described it as a horrible, burning pain, never entirely ceasing during waking hours. It was as severe at night as during the day, and for weeks she secured very little sleep. There were occasional remissions of pain but never complete ease. Hyperæsthesia was as intense as the pain—the slightest touch causing increased suffering and twitching of the muscles. This supersensitiveness extended from the knee to the tips of the toes, but was greatest along the spine of the tibia and over the dorsum of the foot. There were also almost constant muscular movements of the foot, which were greatest at the periods of greatest suffering. She could not bear the weight of a sheet. The extensors of the foot were in a state of tonic spasm, causing a more or less pointed toe. Pressure over the sciatic nerve between the tuberosity of the ischium and great trochanter aggravated both pain and muscular twitching.

About six weeks from the date of injury a peculiar glossy condition of the skin appeared. It looked as though it had been polished or varnished and was destitute of hairs. In appearance it was mottled in patches, the color varying from natural to purple and mahogany-red. The epithelium was in places partially lost, leaving the cutis exposed. There were no wrinkles. The surface was so smooth and shiny that the reflection of bodies held near it was distinctly seen. Several crops of vesicular eczema appeared in patches during the intensity of the disease, which were attended by slight amelioration of the pain. Both the pain and hyperæsthesia reached their height during the fifth week, and then gradually lessened, but did not entirely disappear for three or four months.

After the climax of the disease was reached the vesicular eruption ceased, but the glossy skin remained for nearly four months undiminished, and at the present time, ten months after the injury, has not completely disappeared. There was from the first some swelling of the ankle, which has not entirely subsided.

An interesting feature of this case, showing the disturbance of nutrition, is the arrest of the growth of the nails of the left foot for almost ten months.

The suffering in this case was the most unmanageable that I have met. No local application, except fomentations of hot water, afforded the slightest relief, and they very little. Ointments of morphia, atropia, aconitia and lead, many anodyne liniments and fomentations were tried and abandoned as valueless in controlling the horrible pain. Counter-irritation over the inflamed joint was resorted to without perceptible benefit. The patient was opposed to the internal use of anodynes, and bore her suffering with the greatest fortitude for weeks. This peculiar condition of the skin is explained by a local neuritis of the sciatic nerve near the injured joint.

Case II.—J. B., colored, male, aged fifty-six, was injured in the explosion at the West Chester Electric Light Works, December 14, 1887. His injuries consisted of several lacerated and contused wounds of the scalp, face and legs. These were inflicted by bricks from the falling smoke-stack, and were filled with mortar. There were also several superficial burns from hot brick. After thorough cleansing and dressing with iodol and carbolized gauze, the wounds healed without delay, except one on the outer side of the right leg, an inch below the head of the fibula, which remained tender, and was a week later in healing than the others.

About two weeks after this wound closed, the man began to complain of a burning pain in the outer side and front of the leg, extending over the back of the foot and toes. The greatest suffering was at the bend of the ankle, where bullæ formed. They contained bloody serum, and left ulcerated surfaces which soon healed, to be followed by other vesicular patches. The skin over this region was thin, shiny, very smooth, free from hairs, and mottled, varying in hue from a light to a dark brown. It was very sensitive to the touch, and local applications afforded no perceptible relief. Anodynes were administered to secure rest, but with imperfect results. As soon as these patches began to discharge their bloody serum the pain diminished. By March 1st the pain had partially subsided, but the eczematous crops still recurred. April 1st the pain and eruption had disappeared, but the skin had lost none of its glossiness. There was some swelling of the part, but none of the muscular twitching that formed so distressing a feature of the former case.

The disease was limited to the distribution of the peroneal nerve, and was doubtless due to a neuritis—the result of the injury previously described. In the former case the sciatic nerve was injured by the broken femur, which must have been greatly displaced by the patient's effort in going up-stairs. Injury to a great nerve in fracture of the thigh is rare. Dr. Mitchell says (*Injuries of Nerves*): "As regards the femur, lesions grave enough to break and displace fragments from one end of the bone so as to injure a great nerve are rarely seen except as the result of machine or railway injuries. He relates a case of double fracture of the neck of the femur, reported by Mr. Swan. The patient survived two months. 'There was intense pain which proved to have been due to direct injury to the sciatic nerve by the broken bone.'"

Drs. Morehead, Mitchell and Keen, in the *Report of the United States Hospital for Nervous Diseases*, give an excellent description of glossy skin. Previous to this report, Sir James Paget distinctly described this peculiar condition of the skin, and it had been noted as early as 1810 by Mr. Alex. Denmark. An exhaustive description of the malady may be found in Dr. Mitchell's *Injuries of Nerves*.

DIETETIC MANAGEMENT OF THE SUMMER DIARRHŒA OF INFANTS.[1]

By ARTHUR V. MEIGS, M.D.,
physician to the Pennsylvania Hospital and to the Children's Hospital.

It was with much pleasure that I accepted the flattering invitation of your Chairman to be present and participate in the discussion of the very interesting question of this evening, though I confess I feel some trepidation when I contemplate the task I undertake, for I fear what I shall say may not coincide with the opinions held by many of my hearers, and yet, having undertaken to give my views, I cannot, in honesty, avoid what seems to me perhaps the most important of all questions connected with the subject—the use of milk. For only by free discussion, with the outspoken expression of conflicting opinions to sift the various views and rouse interest in the subject, can the real truth be reached. The question is one to which I have given a good deal of attention, both from its practical and its theoretical aspect, having had for a number of years a large experience in the treatment of the disease amongst the poorer classes, while connected with the out-door department of the Children's Hospital of Philadelphia, beside attending a fair number of cases in private practice, and for two or three years I bestowed a large share of my leisure time upon a study of the chemical analysis of human and cow's milk. According to my understanding of my subject, it was not intended that I should confine myself to a discussion of the dietetic management of acute cholera infantum alone, but should include that of all cases of the summer diarrhœa of infants.

Perhaps I can best make plain what I wish to say by first describing what I consider proper dietetic management of the complaint, and then giving, as briefly as may be, the reasons.

When called upon to treat a case of any form of

[1] Read before the New York Academy of Medicine, Section on Pædiatrics, June 27, 1888.

summer diarrhœa, the first question to be asked is—What food has the infant been taking? If it has been nursed, we should be very careful in making any radical change, and should only do so if there is positive ground for believing that the attack is the result of some fault in the milk and not of the hygienic or atmospheric surroundings, other than those connected with the food. As yet, I am quite unable to bring myself to believe that, even in cases of acute cholera infantum, it is good practice to take away from the infant the milk of its mother, if she is a healthy woman and the child has previously thriven upon it. Therefore, as routine practice, and when there is no direct reason to suspect the milk of the nurse, I should continue to have the child suckled for its main nourishment.

As adjuvants, and very important ones, the use of water and stimulants, and perhaps some supplementary food, may be necessary. The administration of water is very useful, for often the child frets to be nursed frequently because it is thirsty, and thereby gets too much food and overtaxes its already greatly irritated stomach; whereas, if water is given, the system obtains what it really needs and nothing more; its systematic administration, therefore, should always be directed in cases of choleraic diarrhœa. In speaking of the use of stimulants, it may be thought that I am departing somewhat from my subject and trespassing upon the ground of the therapeutic management of the disease, but to me it has always seemed that stimulation in these cases is more nearly allied to dietetics than therapeutics. Such being my view, it may, perhaps, be permitted to me to say that I look upon stimulation as of the utmost importance in the severe forms of diarrhœa, and that it is well in such cases to give a teaspoonful of good brandy or whiskey in a tumblerful of water, three or four times a day (a young baby cannot often be induced to take more than this quantity in twenty-four hours, nor would it be well, except in cases of very unusual severity, to give more), or to give thirty drops in sweetened water every two hours, as may be judged best, according to the stage of the disease or indications in the individual case dealt with. In regard to the administration of other food beside that of the milk of the mother, it must first, as already said, be determined whether there is reason or not to believe that the latter is in any way faulty. If the milk of the mother is decided to be faulty, and has, therefore, been partly or wholly the cause of the attack, the nursing must at once be stopped and the infant fed artificially in the way that will presently be described under the head of the ordinary dietetic treatment of the disease for hand-fed infants. On the other hand, even when the mother's milk is, for every reason, believed to be good and to have been in no way the cause of the illness, it will often be found of advantage to give two or three times a day half an ounce of raw beef juice with a pinch of salt in it; or, again, wine whey will often be retained by an irritable stomach, and one or two ounces given two or three times a day will be found to aid in the cure.

The dietetic treatment of summer diarrhœa in hand-fed children, and in those who, having been nursed, must suddenly be weaned, because it has been decided that the mother's milk was so bad as to be no longer a fit nutriment for them, is a subject of both great importance and difficulty. If the case is one of an infant previously hand-fed, the first thing to be determined is whether the food has been in any way the cause of the attack. The sources of supply and the condition of the food, as it is found in the bottle from which the infant takes it, must be carefully investigated.

The basis of almost all foods for infants is cow's milk, and the question of their artificial feeding, both in health and disease, therefore, largely hinges upon its composition and methods of use, unless we are prepared finally to accept the new views upon the subject, which are the result of studies of the chemistry of, and the microörganisms found in milk; in which case, if we push our belief to its furthest limit, the question of the dietetic treatment of summer diarrhœa becomes a very easy one to solve, for we have only to decide upon the form of meat broth which shall be administered. As I am unable to accept the view that the best treatment in all cases of summer diarrhœa, or even of the choleraic forms, is at once to stop all milk-foods, and put the infant upon an exclusive diet of meat-broth, it becomes necessary to say something of the use of milk.

The great and cardinal principle to be remembered under all circumstances, in using cow's milk for infants, is, that it contains a much larger percentage, about three times as much, casein as does human milk, and that it must, therefore, always be diluted. The word casein is used advisedly, for it is an old term and quite as good a one by which to express the various nitrogenized principles contained in milk as any one of the newer names. Where cow's milk is diluted the amount of fatty material is reduced to less than that contained in human milk, and, therefore, something must be done to increase the quantity of this constituent, which is easily effected by the use of cream. The sugar in undiluted cow's milk even is less in amount than that in human; sugar, therefore, must be added. Lastly, and a matter of great importance, cow's milk is acid, while human milk is alkaline, and this difference should be removed. The addition of lime water is the best known means of effecting this end.

This is not the proper place, and the time is insufficient, for me now to go deeply into the arguments in regard to this subject, more especially as I have already done so in my work upon *Milk Analy-*

sis and Infant Feeding, and, therefore, it is only possible for me to give somewhat dogmatically, and without expressing the reasons, my conclusions upon what constitutes good dietetic treatment of the disease. It has been my habit in cases of diarrhœa, as well as for infants in health, to depend upon milk-foods mainly (it goes without saying, that in all instances the milk must be absolutely untainted when given to the child). The food I have recommended, and from the use of which I have had very satisfactory results, was the outcome of a study of the subject, both from the clinical and the scientific or theoretical standpoints. Clinical experience taught me that dilution, with the addition of cream, sugar and lime-water, gave good results, and when by chemical analysis I learned that such a mixture contained the same constituents as, and in almost the exact proportions in which they exist in human milk, I became entirely convinced, and the more I have pursued the subject the more satisfied have I become.

Since writing my book, I have further studied the subject, and have come upon the following method for the preparation of the food, which is easier and, therefore, better than that formerly recommended. One quart of milk is placed in a vessel, a tall narrow pitcher is best, and after standing for three hours the upper pint is slowly poured off. This contains the greater part of the fat (cream), and when the child is to be fed there should be mixed together three ounces of this cream, two ounces of lime water, and three ounces of sugar water, which must be made in the proportion of eighteen drachms of milk sugar to a pint of water. This makes eight ounces of food, which, of course, is much too large an amount for a young infant or one that is ill. If, therefore, the infant is young, only two to four ounces will be needed at each feeding, and only that quantity should be prepared, the same proportions, however, being observed and the measure used a tablespoon or dessertspoon, as the case may be. The directions given are those for the feeding of a healthy infant between two weeks and six to nine months of age, and are mentioned only to serve as a basis for what should be given those suffering with summer diarrhœa.

In infants in health, it is very important that we should take a lesson from nature, and not increase the strength of food until the child is six months to a year old; and in cases of summer diarrhœa, or if there is any threatening of it, this, I am sure, is absolutely essential, as young infants can seldom when well, and still more rarely when suffering with diarrhœa, digest without injury the large quantity of casein contained in undiluted or very slightly diluted cow's milk. The food described, therefore, serves as the basis upon which I rest my method for the dietetic treatment of the disease, and with it as a base I vary the food in many different ways to meet the needs of different cases.

Of the four things mentioned as necessary to make cow's milk a fit food for infants—to dilute, and add cream, sugar and lime-water, the least essential probably is the use of milk sugar. In cases of diarrhœa, it occasionally becomes advisable to use cane sugar, and if this is done one-third less should be used than the amount recommended of milk sugar. An excellent food for children of six months old or more, and one which has been largely and very successfully used at the Children's Hospital in cases of summer complaint, is that which was recommended by the late Dr. J. Forsyth Meigs: equal parts of milk, cream, lime water and arrowroot water (the last to be made of a teaspoonful of arrowroot flour to one pint of water), and a small quantity of cane sugar; the amount of this to be given and the frequency of the feedings to be such as the individual case requires. The addition of some starchy material or dextrin is of great advantage in many cases, whatever may be the mode of its action, whether mechanical in separating the particles of the milk, or local upon the mucous surface of the bowel, or if its absorption and assimilation has a beneficial effect. One of the best is arrowroot, and the old flour ball, made by boiling common wheat flour in a bag for many hours until it becomes hard, and then grating it, is excellent. Barley, prepared as has been recommended by Dr. Jacobi, may be found exceedingly useful. Of all the baby foods that are manufactured, the only one that has given me such results as to encourage me to persevere in its use for any great length of time and to recommend it extensively is Mellin's Food. This has in many cases proved most useful, and should be given in the proportion of a teaspoonful to four ounces of whatever milk food is being used. It has never seemed to me necessary to dissolve it separately in hot water, and I have generally had it added directly to the milk when warm, for it is readily soluble.

In some cases, excellent results will be attained by taking away all forms of milk and administering animal broths alone; but in my experience this has been the exception rather than the rule, though it is one of the expedients which should always be tried in severe cases which prove unmanageable by the ordinary methods. In my own cases, I have very commonly found that children would soon refuse their food if given soups alone, and it is almost as difficult to make a rebellious infant take what it does not want as an adult: again, many infants will vomit the soups as soon as they are given, when, on the other hand, they will take and retain some form of milk food.

It is very important, in treating this disease, that

precise directions be given with regard to how often the infant shall be fed and the quantity to be taken each time. For my own part, I believe the best results will be attained by not making much change in regard to the frequency of feeding in mild cases—that is, a young infant should be fed every two or three hours, a child of six months old five to eight times in each twenty-four hours, and older infants about four to six times daily. In severe cases, however, it is different, and the frequency of the feedings and the quantities must be quite different from what was proper in health. Experience has brought me to the conclusion that it is only in rare and exceptional cases, and then only for short periods (twenty-four or forty-eight hours at the outside), that it is either desirable or useful to administer food oftener than every two hours. The more frequent taking of food than this would seem likely to keep the digestive organs perpetually at work, or even to give them a fresh load before they have had time to dispose of the last taken. My rule, therefore, is, in severe cases, to give a small quantity of food (from half an ounce to three ounces, as it is found the stomach can retain), every two hours. If the case is very critical and collapse or some other form of sudden termination seems so imminent that something must be done, stimulants, which act quickly, will be much more to the purpose than food; as common practice, therefore, it has long seemed to me that more harm is done than good if food is given as often as every hour, or, as I have frequently seen done, every half hour.

In dealing with cases of summer diarrhœa, one of the most difficult things to avoid is the inclination, when some improvement does not show itself very soon after a change of food has been made, to change again before there has been time to ascertain what was the result. Thus, often greatly to the injury of the patient, a second change is made, and to some food not so suitable as the one just stopped, when, if the physician had waited a few hours longer, he would have found that he held the key to the situation. This difficulty is much increased by the fact that parents and nurses are almost always, and naturally so, very impatient, and, if left to themselves, wish to try everything, and then go so fast from one food to another that the possible benefit is lost. In this particular, more than any other, will a ripe experience, coupled with sound judgment on the part of the physician, stand the patient in better stead under these critical circumstances than great learning.

From what has been said, it might be supposed, perhaps, that I had never heard of the immense work that has been done in the study of the microörganisms which exist in milk, and was ignorant of the great discovery recently made of the chemical poison which is found under certain circumstances, and which has been isolated so that it can be seen and handled, thus furnishing us a reasonable explanation of what was so long incomprehensible, the fact that milk and articles of food compounded with it become, now and then, quite virulently poisonous. I should be exceedingly sorry to be thought so culpably ignorant, and it was certainly not want of knowledge that made me speak as I have done. The existence of the chemical poison in milk has been demonstrated, and no reasonable man should pretend to doubt it, and the presence of the microörganisms is equally undeniable it is, however, when we come to reason from these truths that we should proceed slowly and cautiously, and not in any instance commit the error of mistaking our theories or perhaps our conclusions for facts.

Though all that has been claimed in regard to the interdependence of these two facts and the sequence of events from cause to effect *may* be as has been said, to me it seems that the time is not yet ripe for its unqualified acceptance, as there are so very many reasons, both from the teachings of clinical experience and from the clinical difficulties to be overcome, as well as that many excellent theoretical objections occur, seeming to point strongly the other way. An argument which appears to be a very strong one, against the acceptance of the view that *all* cases of acute cholera infantum are due to microörganisms or a chemical poison or both, is that the disease does sometimes attack infants nursed by a healthy woman whose milk there is not the slightest reason to suspect of being diseased and in which the existence of neither microörganisms nor chemical poison has been demonstrated. Now, as it is beyond doubt that such cases do occur, does not the burthen of proof rest with those who make the assertion of the cause?

As practitioners, what we have to do is to meet the responsibilities and the exigencies of the various cases as they come to us, and I think that it would be no advance in our dietetic treatment that we should put all children suffering with summer diarrhœa upon an exclusively animal diet, and that, even in cases of acute cholera infantum, the accumulation of clinical evidence is as yet insufficient to make such a course proper, as a matter of ordinary practice. The use of an exclusively animal diet is by no means a new method of treatment; on the contrary, it is very old, and has been most extensively tried, and it has long been well known that certain cases, that other methods had failed to cure, would yield to it; but it is equally well known that in others, in which it was as thoroughly tried, it failed, and the cure was only effected after a return to milk diet. Now these experiments were made by men with unbiassed minds; they had no theory to uphold or pull down, and they judged the effects by the clinical results obtained, alone. And what conclusion did they reach? That in exceptional cases only the plan

succeeded, but that in the great majority of instances it failed, miserably, and they had to return to milk as their sheet-anchor.

If we drive this theory of the microörganisms being the sole cause of acute cholera infantum to its ultimate issue, in no case would a patient ever recover if the use of milk was continued, for are we not told that they continue to live and thrive in the intestines of the child? And supposing that no therapeutic remedy was administered to effect their destruction, they should grow and increase so long as supplied with the material—milk—necessary to their existence. No one would pretend to deny that many infants recover from cholera infantum upon the old diet of milk. The advocates of the theory are obliged to assume that, owing to some unexplained reason, the soil ceases to be fertile, or that under some conditions the microörganisms, which a day or two ago were active and threatened the life of the infant, have become quiescent and harmless.

For the sake of argument, let me try to put myself in the place of those who are fully convinced that cholera infantum is always due to the action of microörganisms upon milk, and that the further administration of that article of food will necessarily be very injurious to any patient suffering with the disease. I must then, of course, give only animal food; but at the very outset, the doubts and difficulties that beset me in the clinical management of my cases are enormous.

Any one who has tried to feed a diabetic upon an exclusively flesh diet knows that it is always difficult, often impossible, and with infants it is the same; many will refuse to take the broths, others will vomit them with the utmost violence as soon as swallowed; and my past experience tells me positively that some of these same infants can take and retain milk food. Now what is to be done, give the milk or hold rigidly to the routine of meat diet alone? Again, one of the most difficult points we shall be called upon to decide is: What constitutes cholera infantum, and how are we to recognize clinically the difference in cases which approach the border-line between it, at the one extreme, and simple diarrhœa with which almost all teething children suffer more or less in summer, at the other? The decision of this question will often be very difficult, and vastly important, especially in the case of nursed infants, who, if the breast is taken from them, even for a few days, often, for a variety of reasons, cannot be got back to it. Neither chemistry nor bacteriology will afford any aid in a conclusion in any individual case, the clinician being obliged to decide the point on the instant, for his patient would be dead long before the methods of the scientist would enable him to give any answer with regard to the wholesomeness of the food.

Continuing the assumption that it has been proved that microörganisms are the sole cause of cholera infantum, and conceding that all patients suffering with it must be put upon animal diet, it seems to me that we are still very far from the goal where we may sit down and say, now we have reached the end and no change from our present perfected methods need be made in the future. Is it not universally recognized that for hand-fed infants in health there is nothing so easy of digestion and of assimilation as a good milk food, and no plan of diet so successful as a well-arranged and a well-executed one of milk? It seems strange that so soon as an infant becomes ill, and still more as the disease is one of the digestive system, that we must take from it that which every one agrees is the most digestible and perfect food it can have. Certainly the science of therapeutics is lamentably imperfect, and we must never rest until a medicine is found which will so change the digestive processes or modify the milk that the microörganisms shall cease to be able to work injury, and we may again with safety give to infants suffering with this disease that of which they are sorely in need, the food which of all those in the world suits them best.

In conclusion, I can only say that I hope I have not by an expression contrary to the opinions or beliefs, or even prejudices of my hearers, offended any one, for my wish has been to give, with as great brevity as comprehensibility would allow, my opinion as to what constitutes the proper dietetic treatment of the disease, and then such reasons as struck me as most forcible in favor of the correctness of my opinion and as opposed to the contrary view, which seems to have many advocates in the profession, for I am fully convinced that there has as yet been no accumulation of clinical evidence sufficient to warrant the acceptance of the all-meat diet, and it will be the clinical results obtained which must some day give the question its final answer. Further, I do think that even if we were forced to confess that the meat diet must be accepted as a routine treatment, it must be with the understanding that it is only a makeshift, and that we must strain every nerve to discover some means by which we may again with safety continue our patients with cholera infantum upon a diet of milk.

A CLINCAL STUDY OF THE ETIOLOGY AND TREATMENT OF SUMMER DIARRHŒA OF INFANTS.

By SIMON BARUCH, M.D.,
PHYSICIAN TO THE NEW YORK JUVENILE ASYLUM AND MANHATTAN GENERAL HOSPITAL.

The season when this fearful scourge enters upon its annual mission of destroying health and life is upon us, and it is meet that we discuss again, though it be for the thousandth time, this all-important subject.

There was a time when I actually dreaded the approach of summer. So fatal was this disease, that it was my wont in the beginning of the season to pass mentally in review the innocents who in the community in which I then resided were ready for the slaughter by reason of their ages and the method of feeding applied to them.

I had been taught to regard this disease as an inflammation of the gastro-intestinal tract, chiefly as an entero-colitis, which required minute doses of mercury, with opium and poultices, and astringents in the later stages.

The results of this treatment may be gathered from the following extract from my record book, written August 21, 1869:

"Four cases of this disease have proved fatal in my hands this summer, despite of all efforts; besides one I saw in consultation, and several other fatal cases were communicated to me by colleagues. When I reflect upon the inefficiency of treatment in these cases, and by what strenuous efforts and most anxious care those which survived were saved, I am bound to feel that there must be something erroneous in my conception of the pathology of the disease."

As long as I regarded summer diarrhœa as a purely inflammatory disease, the treatment continued unsatisfactory; the mild cases recovered and the more severe succumbed. The prognosis has, however, become more favorable since the faulty character of this theory became apparent, and since the adoption of less active medicinal treatment and more careful attention to the removal of irritating matters; together with a due regard to food and other hygienic essentials.

It is my belief now, that the summer diarrhœa of infants is chiefly, though not solely, due to the indigestion and multiplication of microörganisms which create in the gastro-intestinal tract conditions somewhat similar to those found in wounds to which septic material has had access. As in the latter, we observe heat, redness and swelling, signifying inflammation, with all its concomitants and sequelæ, modified by the position and functions of the parts involved; so have we in the former, inflammations whose disturbing influence is exerted upon the organs involved, and which give rise to the manifestations of so-called entero-colitis.

Certain it is that the theories hitherto prevailing with regard to the etiology of this disease are faulty. They have served to lead us into faulty methods of treatment. Both these propositions I shall aim to demonstrate.

The causes of summer diarrhœa are usually enumerated as follows:

1. Insanitary conditions, such as overcrowding, poverty and filth.

2. Artificial feeding.

3. High atmospheric temperature.

In the light of recent studies on this subject, we cannot accept these causes as playing more than the *rôle* of predisposing elements favoring the development of bacteria, which are the true potential causes of summer diarrhœa.

1st. That insanitary conditions, poverty, overcrowding and filth are entitled only to the claim of predisposing elements, is made evident by the fact that summer diarrhœa is not a disease confined to crowded cities, nor to those localities in cities where large masses of population are huddled together, nor is it limited to the poorer classes, the lower strata of society. Not unlike traumatic fever, it prevails in all localities, wherever the elements favoring its development are in operation. I am aware that this view is not generally accepted, but my personal experience sustains it, for I have observed the ravages of the disease in the dwellings of a rural town, in the isolated log cabins of the plantation negro, where the pure breezes pass freely through large crevices; I have seen it as fatal in the piney woods of South Carolina as in the better dwellings of this great city. Indeed, I may say that my observations on summer diarrhœas have been almost entirely made in the localities and among the people referred to. Although I have treated a few cases in the tenement-house districts of this city, my principal experience has been gathered at Washington Heights, the section which lies north of One Hundred and Forty-fifth Street, between the Hudson and Harlem rivers. Several cases and one death were observed in that lovely suburban group of dwellings called Audubon Park. A more clean, airy and healthful spot cannot be found in this city, and yet, right here, I have encountered cases as severe as in the dwellings of the Germans and Irish in the district beyond it, or in the negro cabins of the South. And, again, I have spent three summers at one of the most popular summer resorts, and here this grim spectre stalked abroad, defying the pure ozone wafted across a broad expanse of ocean.

These observations have demonstrated conclusively that while filth, overcrowding and poverty do increase and enhance the fatality of summer diarrhœa, they do so precisely for the same reasons which would operate in any other septic disease. Overcrowding, poverty, filth and insanitary conditions enhance the fertility of the soil and favor the multiplication of microörganisms which are introduced with the food into the gastro-intestinal tract.

2d. Artificial feeding. That this is a predominating factor in the production of summer diarrhœa has long been accepted by the profession. The fact that the disease is comparatively rare among breast-fed infants established artificial feeding as a prominent predisposing cause. Meinert, of Dresden (*Jahrbuch der K. Krankheiten*, 1884), shows in

his careful statistics that, out of 500 cases of summer diarrhœa, only 4 per cent. were among breast-fed children. Hope informs us that, among 1000 deaths from summer diarrhœa of infants, only 30 were among purely breast-fed infants.

It has long been sought to account for this immense difference by the difference in composition of the milk derived from the human mamma and that obtained from the cow, which is the most universal substitute for the former. But heterodox as it may seem, I am inclined to the belief, which has almost crystallized into a conviction, that this is an error which has been a veritable *ignis fatuus* in the study of this subject. The chemical composition of cow's milk has been investigated again and again, and authors have presented us with tables, each varying from the other, showing the various elements of difference existing between it and human milk. One writer has handed down to the next the same suggestions, viz., so to change by various methods of preparation, dilution, saccharification and even predigestion of the artificial food, as to approximate it most nearly to the natural food. Has the result been adequate to the labor bestowed upon the subject? Are we more successful to-day in preventing summer diarrhœa than formerly? I doubt it. We still find to-day a serious and fatal form of diarrhœa prevailing during the summer months, which we do not encounter during the spring and winter months. *And yet the system of feeding is precisely the same at all seasons.* Infants take cow's milk with impunity throughout the winter months and thrive admirably; indeed, some of the most robust infants have been thus nourished. But when the blighting temperature of summer comes, the scene changes at once, diarrhœa ensues, the baby languishes, and, perhaps after some exceptionally hot day, we are summoned in haste to see it, beyond hope of recovery, or in the inception of an attack which may terminate in a chronic entero-colitis that will sap the constitution and change the robust infant into a mere shadow of its former self. Have we not all passed through this experience? The tolerance of the infant stomach during the winter months is remarkable, and yet this fact has not received the attention it deserves. No complaint is made of the food, unless an attack of indigestion, probably due to overfeeding, occurs, which soon subsides if the food is changed or withheld. No anxiety occurs if such an attack ensues *during the winter months*, but let even the premonitory symptoms of diarrhœa show themselves during the summer months in an artificially fed infant, how different is the experienced physician's prognosis! At once he sees danger ahead, and preparations are made for battling with an enemy, who has so often defeated him that he has learned to dread his first appearance. Why this difference? It cannot, it does not, rest upon the difference in the chemical constituents of cow's milk. Indeed, the valuable researches of Escherich (*Jahrbuch für Kinder Kr.*, Oct. 1887) have shown, what we all have learned by observation (during the winter), that the great hue and cry about the inappropriateness of casein from cow's milk to infantile nutrition has no foundation. Escherich has fed a healthy infant, ten weeks old, on pure cow's milk, one quart per diem, thus giving the stomach a far larger quantity of casein to dispose of than a nursling of the same age would obtain from the breast, with the result, that he found upon careful examination of the feces an almost ideal digestion of the casein. He was so astounded by the outcome of this experiment that he did not venture to publish it, until he learned that Uffelmann and Forster had reached the same conclusions. He thus was led to the emphatic declaration that "there is no doubt that healthy nurslings are capable of utilizing in the most complete manner cow casein in quantities far in excess of their requirements of nitrogen." Examinations of the feces have established this fact as positive in his mind. If albuminoid bodies approximating casein are found in excess in infants nourished with cow's milk, this is the result of habitual overfeeding, rather than an inability of the gastro-intestinal canal to appropriate the cow casein. "After these investigations," says Escherich, "let not another word be said of the digestion of cow's milk being more difficult in the normally developed infant than the digestion of breast milk."

While I would not be willing to go as far as Escherich, I cannot escape the conclusion, that clinical observations, sustained by the chemical investigations here referred to, point to the fact that practically cow's milk is not so illy adapted to the nutrition of infants as has been generally accepted. Hence the reason of its being so potent a factor (either when taken alone or in connection with other so-called foods) in the production and maintenance of summer diarrhœa must be sought in another direction.

3d. High atmospheric temperature doubtless exercises an important influence in the production of summer diarrhœa. Indeed, the name would indicate that this factor is of paramount import. As I have said above, a diarrhœa occurring in a bottle-fed infant, in a temperature of 40° F., is regarded by us with equanimity, while the same disturbance in a temperature of 95° F. at once creates anxiety. In what manner does the elevation of temperature so completely change the prognosis? It has been generally held that the depressing effect of high temperatures upon the sensitive organization of infants, together "with the noxious exhalation from various sources with which the atmosphere is loaded, as a consequence of the heat" (J. L. Smith), explains this difference. But here, too, as in the matter of artificial feeding, we have

probably been searching in the wrong direction. For, while there is no doubt that the depressing effect and the noxious exhalations due to high temperatures are *predisposing* elements, the fact stares us in the face, that nurslings who are as much exposed to these influences as bottle-fed children enjoy so remarkable an immunity from the disease, as Hope, Meinert and others have mathematically demonstrated. True, it may be held that, being more healthfully nourished, they may be fortified against these noxious agencies arising from heat; but if this were the correct interpretation, the difference would not be so immense as 4 to 96 (Meinert) and 3 to 97 (Hope). We cannot, therefore, accept this explanation of the action of high temperature in the production of summer diarrhœa.

Clinical observation has demonstrated that the three factors referred to, viz., *insanitary surroundings, artificial feeding and excessive heat act in unison in the production of summer diarrhœa.* But, while this is true, their *modus operandi* has, up to the present time, been misunderstood. I am almost convinced that the *kind* of food, if it be reasonably constructed with due regard to the physiological functions of the infantile digestive tract, would be of minor importance *if we could prevent the access of microörganisms in its preparation.*

The reason why cow's milk prepared in the old-fashioned way, by dilution, warming and sweetening, does not produce serious diarrhœa in winter, while it almost invariably does so in summer, lies not so much in its large amount of casein and fat, and smaller amount of sugar, etc.; but more in the fact that *a high atmospheric temperature favors the development and multiplication of bacteria.*

It is a matter of common observation that milk turns sour more readily in warm weather than in cold. Soxhlet has shown this difference in mathematical degrees, viz.; that milk curdles 330 times faster in a temperature of 95° F. than at 58° F. Here we have the whole matter in a nutshell.

It was first shown by Pasteur, as long ago as 1857, that the curdling of milk is due to a bacterium lactis; and since that time Schröder, v. Dusch, Lister, Hueppe, Marpman, Löffler and others have labored effectively to clear up the subject of milk bacteria. It has been demonstrated that milk sugar is transformed into lactic acid by the bacterium lactis, with development of CO_2, and that not all milk fermentation is due to a single organism.

But the most important discovery in connection with this subject was made by Lister, who, in following up the original researches of Pasteur, ascertained that a drop of sour milk, introduced into urine or into any appropriate culture fluid, gave rise to a remarkable development of bacteria of various kinds and degrees of mobility, and that a drop containing any of the latter would again produce souring of milk.

It requires no great stretch of deduction to believe that, when the various bacteria rapidly developed in warm weather in cow's milk after it leaves the udder reach the stomach of an infant depressed by excessive heat and perhaps by insanitary surroundings, their number may be rapidly multiplied; fermentation may thus be set up with evolution of gases, which in turn fructifies the soil for their increased development. The proper breaking up of casein is interfered with and it passes into the intestinal canal, carrying with it masses of bacteria, which, joining those present in the canal, become the parents of such large colonies of various types, that the intestinal tract becomes inflamed and ptomaines are formed, thus giving rise to the local lesions and general phenomena of summer diarrhœa.

That this is not a theory unsupported by demonstration is shown by the investigations of Baginsky, Nothnagel, Booker, Escherich, Hayem, Lesage, Le Gendre and others. In his work (*Die Verdauungskrankheiten der Kinder*, published in 1884), Baginsky refers to his microscopic examinations of the intestinal walls in follicular diarrhœa and cholera infantum, with a view to ascertain if the pathological lesions are coincident with the appearance of microörganisms in the intestinal canal and if this connection is of etiological significance. After carefully eliminating, by processes which he describes, all "cadaveric microörganisms," he succeeded in separating four different varieties, which he describes clearly and which, he is sure, are not post-mortem developments. He says that some of these so closely resemble those found in the stools that the conviction cannot be avoided that they are the same. The abundance of these microörganisms in the feces of the initial catarrh and their reappearance in the intestinal walls in cholera infantum lead him to the view that *they are essential factors in the production of these diseases.*

Booker has studied twenty-three varieties of microorganisms in the different forms of summer diarrhœa in children. The authors mentioned above have entered fully into this subject; but the aim of this paper being purely clinical, I must be content with a simple reference to their work.

These preliminary remarks on the probable causes of summer diarrhœa are necessarily brief, being intended simply as a prelude to the description of treatment. It would follow, from what has been said, that by the light of modern investigation we may recognize the erroneousness of our former management of these cases, and also the reason why such remedies as evacuants, mercurials, bismuth, creasote, etc., have afforded good results in many cases, while the opium treatment, which aimed to cure by quieting the peristaltic action, failed to accomplish any permanent result.

The treatment may be divided into prophylactic, curative and symptomatic. In the prophylaxis of

summer diarrhœa the selection and preparation of the food stand first and foremost.

How can we select an infant food that will fulfil the chief indications of preventing the access of bacteria to the stomach?

We know that human milk is aseptic, hence it rarely produces fermentation and consequent diarrhœa, and I believe *this is its chief claim* to being the foremost food in the prophylaxis of summer diarrhœa. We know, also, that the best substitute for human milk is some preparation of cow's milk, and this is also aseptic when it leaves the udder. Human milk reaches the infant's stomach directly without admixture, while cow's milk reaches it after exposure to various contaminating influences. In the first place the act of milking alone must favor the production of bacteria. I speak from personal observations (having owned a herd of Alderneys) when I say that it is utterly impossible, by the means hitherto in vogue, to avoid contamination. The stable may be ever so neat, the hands of the milker scrupulously clean, the teats carefully washed; but the act of milking involves a kind of churning of the milk deposited in the bucket by the stream propelled into it from the teats. This churning produces a large quantity of foam whose chief constituent is air containing the impurities which the most punctilious attention to cleanliness fails to eliminate from the stable or cow-yard. Besides these, solid particles, hair, etc., mix with the milk, which, though they may be removed by the customary straining, have lain long enough in the milk to contaminate it.

We who realize the necessity of constantly irrigating a wound during a surgical operation, in order to prevent its becoming septic from the air of even the most cleanly operating-room, must appreciate how utterly futile all efforts are to maintain the aseptic character of cow's milk as it flows from the udder. If we cannot fully accomplish such an aim, however, it is proper that an effort be made to diminish the chance for contamination by insisting upon scrupulous cleanliness of the stable, the cow, the milker and the milk receptacle. A bucket has recently been invented which is provided with a rubber cover and thus prevents to a great extent the gross contamination of the milk. The milking-tube would be very useful also, because by it the milk could be made to flow directly into a bottle; but this mode of milking is adapted only to cases in which a small supply is required by persons who own a cow.

The feeding and management of the cow are important, but can only be referred to here without entering into details.

The method recommended in 1819 by a German physician, Dr. Twierlein, of utilizing the goat as a wet-nurse, possesses considerable merit. It may be a troublesome method and, æsthetically, an absurd one. But in view of the fact brought out by the bacteriological researches referred to, the practice deserves a fair trial. Goats may be selected that have been rendered docile by training and practice when quite young and thus become useful for directly nursing the infant. Some inventive mind may devise a long nursing-tube with exhausting cup and nipple-shield, which may enable the infant to lie upon the mother's lap and draw its nourishment without being placed in contact with the animal. In view of the immense importance of this subject, our foundling asylums might very properly undertake experiments in this direction. It is certain that far more valuable results may be expected from experiments in this direction than from any therapeutic research or chemical investigation of other artificial foods.

Next in order, to prevent the access of contaminating matter, comes the destruction of such germs as may have been produced already, and which, if left alone, would surely go on and multiply until their presence is demonstrated by souring. Sterilization of cow's milk must and will be a most valuable preventive of summer diarrhœa. Unfortunately, however, the directions hitherto published for the process are either too complicated or too indefinite to be of practical utility in the household. Soxhlet's apparatus nearly fulfils the indication, but it is cumbersome and expensive. Rotch, Jefferies and Caillé have given directions for steaming or boiling the milk from fifteen to twenty minutes, and they have succeeded in producing a milk which does not turn sour for a long time. The fact that such milk failed to turn sour is accepted by these able and conscientious writers as evidence that the milk is sterilized. But this is an error as Pasteur, Hueppe, Löffler, Lister and others have clearly demonstrated. Pasteur has shown that after boiling milk fifteen or twenty minutes the bacteria are indeed killed, but there is a development of infusoria *which do not render milk sour*, but which may nevertheless separate the casein *under an alkaline reaction*. Löffler found that, after boiling milk ten to twenty minutes and allowing it to stand, he was able to cultivate at least four different kinds of bacilli capable of producing spores, growing in milk and precipitating casein, *under alkaline reaction* (*Berl. klin. Wochenschrift*, 1887, p. 630). Schröder and von Dusch have demonstrated, and Pasteur has confirmed their conclusion, *that boiling is insufficient for the destruction of bacteria and spores, but that a continuous exposure for half an hour of the milk to a temperature of 130° C. (266° F.) is required to sterilize milk completely.*

Here, then, we have a standard for practical purposes. This may explain, by the way, why Caillé, in his valuable experiments (*Dietetic Gazette*, April, 1888), did not obtain quite as good results from his method as from boiling milk in Soxhlet's apparatus for thirty minutes. The latter, boiled under pressure, remained good eighteen days, while the milk he

boiled fifteen minutes only in open bottles was sour after five days, because it never reached a temperature above 212° F. As the absence of acidity, by taste or smell or litmus test, does not prove the complete sterilization of milk, it cannot be asserted that the milk in these experiments was so sterilized.

Fortunately the boiling of cow's milk is a great advantage, inasmuch as "boiled milk produces a much finer coagulum and is to be preferred otherwise; while concerning the length of its stay in the stomach, its behavior in the intestine, and the abnormal fermentation processes, there are no definite observations, we may regard it in these respects as the same as mother's milk" (Escherich, *Journal für Kinderk.*, October, 1887). This is not a recent discovery, however, inasmuch as A. Jacobi advised boiling of milk in 1875 already, and J. Albu ("Milchnahrung und Milchcuren," 1881) recommends Bertling's apparatus for boiling milk under pressure for twenty minutes. He states that coagulation germs are destroyed, as are also those of tuberculosis, typhus, scarlatina and diphtheria. He also states that cow-casein is made more soluble and digestible. His experiments and results have been repeated by Salkowski, who at the instance of Virchow made investigations of Boesken's process of boiling milk under pressure. Soltmann (*Berl. klin. Woch.*, May 29, 1882) says that boiling milk in Bertling's apparatus destroys germs and renders the casein finely flocculent. Reichman (*Archiv für klin. Med.*, Bd. 14, No. 6) experimented on nine adults in the digestion of milk, and found that while 10 ounces of raw milk left the healthy stomach four hours after being imbibed, boiled milk was digested in two and a half hours, and that the casein lumps were much finer in the latter. Smaller quantities, as 3 ounces of boiled milk, were digested in forty-five minutes. I have recently had occasion to ascertain how rapidly boiled milk, taken hot, is digested. I had the stomach of a dyspeptic washed out two hours after taking twelve ounces of hot milk, and found no curds, although mucus was abundant. Hence, boiling milk for infants will not only facilitate digestion, by softening the casein, but, if the boiling can be done under strong pressure, so as to raise the temperature to 266° F., it will also completely sterilize the milk. As the latter cannot be accomplished in a simple apparatus, we may approximate it by boiling the milk, in imitation of Soxhlet's plan, in tightly stoppered, strong glass bottles. A lower temperature, 230° F., will suffice, if it is continued for two hours (Schröder, von Dusch).

When the facts here referred to receive general recognition in the profession, dairymen will doubtless find it to their interest to obtain proper apparatus for sterilizing large quantities of milk, and delivering it in appropriate, sealed vessels to consumers for the use of infants in large cities.

Next in importance to the proper selection of the food comes the hygienic management of the infant. It is a well-known fact that impure air, overcrowding and want of cleanliness conspire to render the morbidity and mortality from the disease greater in cities than in the rural districts. The same rule holds good here which, as mentioned above, applies to all diseases connected with microörganisms, whose multiplication is furthered by unsanitary conditions. The infant should receive a daily bath of tepid water, and I regard a rapid sponging subsequently with a sponge wrung out of cold water, followed by rapid drying and friction, as a most valuable aid in preserving the tone and resisting powers of infants over six months old. The baby should be almost constantly in the open air; it should be kept cool, however, and never exposed to the direct rays of the sun in midsummer. A proper amount of undisturbed sleep should be provided, and all disturbances of the nervous system by excessive playing and fondling must be avoided. The infant should vegetate; its days should pass away calmly and in the utmost comfort. Only by thus shielding it against untoward conditions may the helpless, artificially reared human young be safely tided over the dangers which the advent of summer strews in its path. Even the poorest mother may execute these simple suggestions with regard to the hygienic management of the infant.

A word may here be said of teething as a predisposing cause of summer diarrhœa, because necessity of proper management of the so-called dangerous period is so often urged upon mothers. Chapters have been written on this subject by the older authors, but the gum lance has happily been relegated to the drawer containing useless instruments. May it ever remain there!

Teething requires no special hygienic management, certainly not the aid of the gum lancet. While it may be true that during the evolution of the teeth, the nervous system and probably the digestive organs are in a more or less erethic condition, the fact must not be lost sight of, that this is a natural process which in the large majority of cases proceeds without any effect upon the system, provided there be no other disturbing element in operation. We do not encounter diarrhœa from teething in midwinter, nor later in life when the digestive organs are no longer in a susceptible condition.

The second summer is usually dreaded. The reason is obvious: even a breast-fed infant will then be weaned, and be subjected to the influences of food whose preparation or selection may be improper. The indiscriminate use of articles of food obtained from the table of its elders must be prevented, and ordinary hygienic rules, referred to above, must be enforced in order that diarrhœa be prevented during the teething period.

In connection with prophylaxis of summer diarrhœa, attention to the infant's mouth is important. Escherich in speaking of the normal digestion of the infant says:

"In the mouth the germ-free human milk undergoes no change, except its admixture with saliva and with the *bacteria residing in the oral cavity, which surely cannot be without significance in the development of many mycotic intestinal troubles.*"

It is advisable, therefore, during the summer months to cleanse the mouth with a weak solution of boric acid or salicylate of sodium before the baby nurses. Sudden changes of temperature, which are liable to occur at night in August in this climate, and to which cases of diarrhœa may often be traced, are best guarded against by a flannel bandage around the abdomen and the constant use of socks.

Having considered the prophylaxis of summer diarrhœa in the light of the modern theory of its etiology, we may now proceed to the consideration of its curative treatment.

While it may be interesting scientifically to divide the summer diarrhœa of infants as Lesage and others have done, into several types, it will be of little practical value, since the fact remains that true summer diarrhœa is chiefly due to the presence of bacteria of various kinds which set up in the gastro-intestinal canal fermentation and consequent inflammatory action, resulting in lesions which are pretty uniform in character, and objective manifestations.

The indications of treatment are:

1st. To diminish or remove the source of bacterial supply.

2d. To neutralize the disturbance produced by the bacteria.

3d. To remove them from the intestinal tract.

4th. To meet the nervous prostration, inanition, exhaustion and other manifestations due to the diarrhœa.

1st. To accomplish the first object will only be required in an artificially fed infant. A wet-nurse should, if possible, be procured. This being impossible, it is necessary to look into the mode of preparing the food supply. Sterilization of the milk and scrupulous attention to its preparation for the bottle are of the utmost importance, because in the diseased condition of the gastro-intestinal canal, which now contains quantities of fermenting material, bacteria introduced by the food will multiply more rapidly, as Lister has shown by his experiment of the effect of a drop of milk containing the bacteria of fermentation on any culture fluids. Even if vomiting be not present, the withdrawal of milk, for a short period, will be of great value. Barley-water, rice-water and meat broths, which have been deprived of fats, and which have been thoroughly boiled for half an hour, and rapidly cooled just before using, offer an excellent substitute for milk. A solution of white of egg in water, which has been sterilized by long boiling and cooled, one egg to the pint, taken cold, and in small quantities, is also a valuable nutriment, as it may be absorbed without requiring digestion. This may be continued until the stools assume a more normal appearance and consistence, when the regular food, or some one of the predigested foods, containing dextrin may be gradually resorted to.

2d. *To neutralize the disturbance produced by the ingested and multiplying bacteria.* If we have nausea and vomiting, rest of the stomach stands first and foremost, far beyond all other remedies, unless it be the cleansing of the stomach by irrigation, as recommended by Epstein. I have had no experience with the latter, but it is doubtless of value, and I shall resort to it this summer. The stomach cannot be at rest until all fermenting material be removed from it. This I have hitherto accomplished by the copious administration, by the spoon or nursing bottle, of warm water, to which a small quantity of salt has been added. It is difficult, however, to execute this treatment. Epstein's irrigation of the stomach, by means of a soft rubber stomach-tube of small dimensions, would certainly be a great improvement.

The enforcement of absolute abstention from food and drink, in the early stage of summer diarrhœa, cannot be too strongly impressed upon the mother. It will require all the *morale* she possesses to execute the physician's directions. She may be convinced by the argument that since everything the baby takes is rejected, it is futile to continue to feed it or give it even water. When practising at Washington Heights it was my custom to send the women who brought their pale and shrivelled infants to me, during my morning hour, with a history of purging and vomiting during the preceding night, to a certain broad-limbed tree standing upon a rocky elevation at 165th Street, and instructing them there to await my arrival. Having neither food nor drink with them, the complete rest of the stomach and bowels was enforced, and this together with the exposure to pure air, under the shade of the tree, usually so restored these little ones in a few hours, that I have found them asleep and free from vomiting when I drove up to the extemporaneous sanitarium.

It is not only difficult to convince the mother that baby will not starve to death, if food and drink are withheld for six or eight hours, but I have known intelligent physicians to labor under the same delusion. I well remember meeting, in consultation, a bright young colleague in the case of the largest six months' infant I have ever seen. The baby, though reared on the breast, was suffering from vomiting and purging, chiefly the former. Vomiting had been uninterrupted for twenty-four hours, and had

lately produced serious collapse manifestations, which alarmed the attendant. But despite the refusal of the infant to take the constantly proffered breast, the anxious attendant had milk drawn from it, and forced the child to take it from a spoon. Complete abstention from this course reëstablished the integrity of the stomach, and change of food to broth, and, afterward, diluted cow's milk, together with rectal irrigation, restored the child to health.

There are few cases of vomiting which will not yield to complete abstention from food and drink for a few hours, after the stomach has been thoroughly cleansed. Mustard sinapisms to the epigastrium, and anti-emetic medicines only serve to disturb the patient. If rest does not bring relief, I resort to the old-fashioned Dewees' mixture of

℞.—Magnesiæ . . . . . ℥ ss.
Spts. ammon. arom. . . . . ℥ ss.
Aquæ menth. pip. . . . . ℥ ij.—M.
Sig.—Thirty drops every half hour.

This checks fermentation and appears to soothe the irritation effectually. When this mixture cannot be retained at all, a dose of calomel, one-half to two grains, will almost invariably be retained, if administered immediately after vomiting, laid on a teaspoonful of water, without stirring, or placed dry upon the tongue, and followed by a few drops of water. Calomel not only acts as a parasiticide, but fulfils the indication of removing irritating matters from the intestinal canal.

3d. *To remove the bacteria from the intestinal canal* is a leading indication. It is important that all fermenting material which offers a nidus for their development should be swept out. A full dose of castor oil, or when the stomach is irritable a dose of calomel, will remove the entire mass from the upper tract. It will not be necessary to repeat the purgative if it is followed by thorough irrigation of the large intestine with sterilized warm water. I believe that in this procedure we possess a most valuable remedial measure for summer diarrhœa. But it must be borne in mind that irrigation cannot be accomplished by an *enema* of warm water. This would act as an irritant and create additional disturbance. A rubber horse catheter, or a large Nélaton catheter, should be used for this purpose, because its walls are firm and yet elastic, and its length admits of its deep introduction. It should be attached to the pipe of a fountain syringe, containing one quart of water that has been boiled for half an hour, and in which half a drachm of bicarbonate of sodium has been dissolved. The infant is placed upon the abdomen in the lap of an attendant. The tube anointed with vaseline, and firmly held between the thumb and index finger of the right hand, is gently introduced into the anus. The pressure of the fingers is now somewhat relaxed, in order that the water may flow, while the tube is being gently but firmly pushed into the intestinal canal. Whenever it meets an obstruction it should be withdrawn a little, and gently persuaded to pass upward. Sometimes it is more readily introduced when disconnected from the syringe. When the upper point has reached the transverse colon, or cannot be introduced further, it is held quietly until about a quart of water has passed. There will be no distention, because the pressure of the child's body upon the nurse's lap will aid in expelling the water as rapidly as it is introduced. I have occasionally added with advantage one-half grain bichloride of mercury to the quart of water, allowing always an extra pint of plain water to follow the medicated injection, to prevent poisoning.

Expérience has convinced me that thorough irrigation of the large intestine, administered by the physician or by a competent nurse, under special instruction, every three, four or five hours, lessens the number and changes the character of the movements, and produces a most soothing effect upon the patient. I have frequently seen infants, who had been tossing in pain, purging and vomiting, drop into a gentle slumber, while the water was still flowing. Almost invariably a quiet slumber follows the irrigation, the purging ceases, or is much modified, and the whole aspect of the case is changed. The result of the irrigation is the removal of bacteria, mucus, undigested food and fermenting material. Cantani has in the treatment of cholera succeeded in reaching the stomach by such irrigations. J. L. Smith has found the lesions in summer diarrhœa

"in all but one of eighty cases in the colon, in thirty-nine, nearly or quite through its entire extent; in fourteen it was confined to the descending colon; the portion of colon most frequently inflamed is just above the sigmoid flexure."

"In the large intestine, the cæcum, sigmoid flexure, and upper part of rectum were the portions in which the most advanced lesions were met with. In the small intestine the changes were generally limited to the lower part of the ileum," says Holt in The Medical News of June 9, 1888.

Hence we may safely assume that the irrigations reach most of the diseased surface, and thus we follow the indications of modern therapeutics, to treat local troubles by local measures, as far as possible. The inflamed parts are not only soothed by these warm irrigations, but the *materies morbi*, which maintain the disease, are removed and neutralized. An incidental advantage, too, is the stimulation of the hepatic function, which this imitation of Krull's injections produces.

While I have, in cases of dysentery, resorted to the addition of bichloride of mercury with advantage, I regard the addition of antiseptics to the irrigating fluid as unadvisable, inasmuch as the solutions can-

not be made sufficiently concentrated to effect the destruction of germs and spores without endangering the integrity of the mucous membrane, or menacing the system by poisoning from absorption. Further investigations may develop a perfected medicinal irrigation. For instance, Cantani's method of tannin irrigations in cholera may be here initiated. In chronic and subacute cases these may be valuable, by local astringent action.

The internal administration of antiseptics, especially salicylate of sodium and naphthalin, has found able advocates, but if we consider how large a quantity would be required to sterilize so extensive a surface, we can scarcely expect any decided results from this practice. My own experience is confined to small doses ($\frac{1}{64}$ grain) of bichloride of mercury, and large doses of bismuth, both of which have proven valuable, chiefly in subacute or chronic cases; the former when the stools were clayey and offensive, the latter when they were thin and choleraic.

I must say, however, that in recent years it has been my constant aim to eliminate medicinal treatment from the management of acute summer diarrhœa, as from other acute diseases. It is of paramount importance to maintain the integrity of the stomach, which must be more or less impaired by the administration of drugs. When the stomach is restored sufficiently to receive and retain anything, I regard the introduction of food as far more important. Medicines should be administered *per rectum*, if possible, or avoided altogether. Doubtless our predecessors of the Meigs, Dewees and West school have had good results from "antiphlogistic" doses of mercury, because its antiseptic and purgative properties removed the bacteria and irritating matter, but they found it necessary to guard it by the addition of opiates, to prevent harmful purgation, while they "stimulated the liver." If we can disinfect, cleanse and soothe the intestinal tract, and at the same time "stimulate the liver" by irrigations, the necessity of medicinal remedies becomes less pronounced.

4th. *To meet the manifestations due to the diarrhœa, and probably to absorption of ptomaines* is a plain indication. Prostration of the vital powers is often rapid and pronounced, threatening a speedy, fatal issue in many cases, from the very inception of the disease. I confess that, until recent years, the true cause of this alarming condition escaped me. Since the recognition of high body temperature as a cause of the prostration, the prognosis of these cases has become far more favorable in my hands.

An elevated temperature range frequently marks the advent of the summer diarrhœa, especially the more alarming types. Indeed, if the rectal temperature were more systematically observed, it would be discovered that a large number of severe cases are ushered in with and maintain a temperature ranging from 102° to 106°. So deceptive are the cool skin (especially of the extremities) and the clammy sweat produced by relaxation consequent upon the nausea, vomiting and diarrhœa, that the high internal temperature is liable to escape observation.

Since I have, during the past eight years, made it an invariable rule to ascertain the exact rectal temperature, I have again and again been surprised by the presence of hyperpyrexia when I least expected it.

The most gratifying result of this practice has been the comfort and improvement of the patient accomplished by the reduction of the high temperature.

I have not resorted to medicinal antipyretics with sufficient frequency to offer reliable deductions. But the graduated cold bath, reduced from 95° to 80°, and continued until the thermometer in the rectum registers a decided fall of temperature, has brought me results which I have obtained from no other remedy. The reduction of temperature, if it can be maintained for twenty-four hours, and the stimulus of reaction from the cold-bath will, in acute summer diarrhœa, completely change the entire aspect of many cases. Vomiting and diarrhœa often cease, the most alarming head symptoms, restlessness, jactitation, screaming and squinting, are almost invariably removed or modified; sleep follows, and convalescence may be established in a brief time, if the cold-bath is resorted to early. After the bath the child should be wrapped in a sheet wrung out of the bath water, reaching from the neck to the knees, while the warmth of the feet is maintained by hot-water bags.

This paper being clinical, I will not enter into a theoretical explanation of the action of cold water in these acute cases. The following case will illustrate the method of administration and its results:

P. S., infant, six months old, vigorous and healthy, living in one of our best houses on the banks of the Hudson, had been weaned one month. Since that time he had been suffering from occasional diarrhœa, which had been treated with more or less success by my friend, the late Dr. Frothingham, and myself for a week. On July 30, 1881, vomiting and choleraic stools prompted the mother to summon me in haste. I found the little fellow a changed being; his features were pinched, skin cold and clammy, eyes sunken; he could retain nothing, the bowels ejected a thin, green fluid about every half hour, sometimes more frequently. Drs. A. Jacobi and J. Lewis Smith were summoned in consultation by my request. The former was absent; the latter reached the house about five hours after the messenger was despatched.

In the meantime the symptoms grew more and more threatening, the pulse began to fail, the child lay with upturned eyes, pinched features, rapid, shallow respiration and cold extremities—on the

brink of dissolution. It occurred to me to take the rectal temperature, and, to my great surprise, I found it 106° F. A cold-bath was immediately ordered, although the proposition so shocked the mother that she wrung her hands in despair, lest the infant should succumb to the cold. A large bath-tub was half filled with warm water until the temperature reached 90°. The infant, whose stony gaze indicated the approach of eclampsia or impending dissolution, was submerged in the water, except the head; the lower and upper extremities were held up and chafed. Cold water was turned on, and ice-water was added, while the water was permitted to flow from the tub. In ten minutes the temperature of the water was reduced to 80°. A smile now passed over the baby's face, his eyes lost the stare, and he revived. His rectal temperature began to fall, and in ten minutes reached 100°. He was now wrapped in a cloth wrung out of water at 80°, from neck to knees; hot-water bags were applied to the extremities, and he was carefully covered. He fell into a sweet slumber, from which he awoke when Dr. Smith arrived, to find him rescued from immediate danger. A wet-nurse and careful attention restored the child in a few days.

Inanition caused by the diarrhœa must be met by a cautious selection of food. I have dwelt upon the fact that in health cow's milk, sterilized shortly after leaving the udder, offers an excellent substitute for human milk, and is a good prophylactic against summer diarrhœa, because, as Escherich and Uffelmann have shown, the *healthy* infant is perfectly competent to dispose of large quantities of cow's casein. But, when the digestive organs are enfeebled by disease, cow's casein will not be readily taken up, and will act as an irritant to the bowels. As broths and solutions of albumen can be used only as temporary substitutes, one of the prepared foods, constructed from pure, sterilized, partly pre-digested milk, with a proper proportion of dextrin and sugar of milk, to approximate in food value to human milk, will be found of great value. Here we need a partially predigested food, whose unirritating elements may be quickly taken up by the digestive organs without leaving much residue.

I have reported several cases strikingly illustrating the value of the most recent of these foods two years ago, and I have, since that time, observed similar results in two cases, one of these an infant whose mother had been compelled to accept a position as wet-nurse, and which was being fed on condensed milk. This baby had twenty-five stools a day, and was shrivelling up, when I stopped all nourishment, gave brandy and water, and then put him on the prepared food, which, in a few days, produced a complete change.

Care is requisite in warning mothers not to add milk to these prepared foods containing milk, which they will be tempted to do in order to concentrate the food. It is important to impress upon them the danger of overfeeding in disease as well as in health; to this cause much infantile gastro-intestinal disturbance may be charged. There is no limit to the amount a bottle-fed child takes, except its own free will and capacity. The former is limited by the supply in breast-feeding, hence the latter is rarely overtaxed. But in bottle-feeding the supply is unlimited: hence the quantity should be carefully guarded, and should be made appropriate to the age and digestive powers of the recipient.

Alcoholic stimulants are valuable as aids to tide over the danger of collapse and debility from inanition. Good whiskey and brandy are probably the best. Opiates are the only medicinal remedies that possess absolute effects in checking peristaltic action. I now have little confidence in the various astringents, which I formerly used extensively. As they were usually combined with opiates, it was impossible to judge their intrinsic value. After all irritating matter has been removed from the gastro-intestinal tract, opiates are most valuable measures for allaying the irritation of the intestinal canal and comforting the patient, but their administration has hitherto been too indiscriminate.

47 EAST SIXTIETH STREET, NEW YORK.

MEDICAL PROGRESS.

On Amylene Hydrate.—DR. LARES, in an article in the *Berliner klin. Woch.*, of May 21, 1888, presents the following conclusions:

1. Amylene hydrate is a very useful hypnotic, which may be given in two or three times as large a dose as chloral hydrate.

2. It operates somewhat less certainly than chloral hydrate and morphine.

3. Unpleasant accidents (excitement, slight drunken-like stupor) were very seldom observed. Grave accidents were never observed.

4. A tolerance, relative to diminution in efficiency, was not noticed within three months.

5. The deep and refreshing nature of the sleep obtained was praised oftener than in the case of any other sleep-producing means.

Ectocardia Cured by a Plastic Operation.—PROF. LANNELONGUE, of Paris, recently presented to the Académie des Sciences a very remarkable case of deformity of the chest wall, with ectopia of the heart, which he had dealt with successfully by operation. The patient was a female child, six days old, well formed in every part except the throax. On the front of the chest over the middle of the sternum there was a circular ulcer, rather larger than a franc piece, the base being formed by a yellowish membrane which appeared to be becoming gangrenous. It was already detached from the edges of the ulcer at several points, and thus only imperfectly closed the aperture into the chest. Each beat of the heart pushed it forward, and on applying the finger during systole the hardening of the ventricular walls as they contracted could be distinctly felt. The inner ends of

the clavicle articulated below with the first rib, and appeared to be free internally and above; the sternum was entirely wanting between them. This gap in the osseous wall of the chest extended downward in the middle line; the sternum appearing to be represented on each side only by a narrow strip of bone running downward and obliquely inward, and finally joining the corresponding piece below the median ulcer already referred to. The deficiency in the bony chest wall was therefore of the shape of an isosceles triangle, the apex being below at the ensiform cartilage and the base above at a line joining the inner ends of the two clavicles. The side of the triangle measured one and a half, and the base one inch. The circular ulcer was, as it were, inscribed in this triangle. On inspiration the chest wall corresponding to the malformed part of the skeleton was drawn in, so that a hollow half an inch deep was formed at the upper part; in expiration, on the other had, it bulged markedly forward.

A few days after the little patient was first seen, the remains of the "obturator" membrane at the bottom of the ulcer disappeared; the pericardium was seen to be entirely wanting; the apex of the heart projected outside the chest, and the whole anterior surface of the ventricles was exposed. The hole in the skin became gradually smaller owing to the formation of large fleshy granulations, which pressed on the apex and ventricles of the heart, and it was obvious that immediate surgical interference was necessary to prevent most serious disturbances of the circulation. M. Lannelongue therefore made two vertical incisions on each side, six-tenths of an inch to the other side of the ulcer; the flaps thus formed were sufficiently loosened to allow of their internal edges being brought together over the opening in the chest wall, where they were fixed by three hair sutures. Only a few drops of blood were lost; the operation was not followed by any constitutional disturbance, and the wound was entirely healed in twenty days. Two months after the operation the child was in perfect health. M. Lannelongue points out that in this way he transformed the case from one of "ectocardia" into one of "subcutaneous ectopia." He thinks it possible that the ectopia, which is at present extra-thoracic, may in time, as the heart develops, become intra-thoracic. Professor Verneuil, in presenting M. Lannelongue's communication to the Academy, remarked that this was the first time such a procedure had ever been attempted.—*British Medical Journal*, May 26, 1888.

The Treatment of Flatulent Dyspepsia.—Pepper, in a recent clinical lecture, stated that flatulence may result from the excessive formation of gas. Under these circumstances, such remedies as sulphurous acid, which is a powerful antiseptic, will be found useful. It may be given alone or combined with small doses of strychnia. He prescribed as follows:

R.—Acidi sulphurosi, . . . ℥iss vel ℥ij.
Strych. sulph. . . . . gr. ss.
Tr. card. comp., . . . ℥ss.
Aquæ, ... ad ℥iv.
Sig.—One drachm after meals, in water.

You may resort to a different class of remedies and give creasote. This is a local stimulant to the stomach, and in atonic cases is of service. It is at the same time a powerful antiseptic and anti-fermentative agent. Creasote is best given one-half or one hour after meals, when the process of fermentation is about beginning. At this time the gastric digestion should have passed through the acid stage, and the contents of the stomach should be neutral or alkaline. Given at this time, the creasote may be advantageously combined with an alkali, as sodium bicarbonate.

R.—Creasote . . . . . gtt. x.
Sodii bicarb. . . . . ℥ij.
Pulv. acaciæ, ... q. s.
Aquæ, ... ℥v.
Sig.—Two drachms one hour after meals.

In place of the sodium bicarbonate in the above formula the subnitrate of bismuth may be employed.

If it is recognized that there is not only a state of atony with a tendency to fermentation, but that there is also a deficiency of gastric power, pepsin or ingluvin may be given. Pepsin is best taken in acid mixtures, and should be given at the acid stage of the digestion. At the same time, if the administration of the drug is postponed for a short time after meals, it comes at a time when the power of the gastric juice is about exhausted.

R.—Pepsin. fort. . . . . ℥ j.
Creasot. . . . . gtt. x.
Bis. sub. carb. . . . . ℥ ijss.—M.
Et ft. pulv. No. xxx.

One of these powders, in a small gelatine capsule, can be given one hour after each meal.

Ingluvin is a powerful digestive agent, and may be substituted for the pepsin. I have found it of service in cases where pepsin does not work well, and I should be disposed to say, where the mucous membrane of the stomach is decidedly irritable.

Again, in this same line of thought, we have agents, like powdered charcoal, which act as absorbents of the gases, and are, at the same time, anti-putrefactive and anti-fermentative in their action. Powdered charcoal, with soda or bismuth, may be given a couple of hours after meals, and in the class of cases of which I have been speaking, may afford a great deal of temporary relief. When charcoal is given, the patient should be informed that it will cause blackening of the stools.—*The Polyclinic*, May, 1888.

Intravenous Injection of Sodium Carbonate in Diabetic Coma.—Hesse reports a case of diabetic coma temporarily improved by the intravenous injection of eight ounces of a 4 per cent. solution of sodium carbonate. He adds three cases collected from the literature of the subject.—*Berliner klinische Wochenschrift*, May 7, 1888.

Intrapleural Injections of Sterilized Air.—At a recent meeting of the Academy of Medicine Prof. Potain presented a patient, a young man twenty-three years of age, who had been the subject of tuberculosis, and who had been admitted into his ward in the month of June last with a pneumothorax and an extensive pleuritic effusion, which were completely cured by a new operative procedure, which consisted in intrapleural injections of sterilized air. Considering that the sudden withdrawal of the totality of the liquid or its extraction in several days

might equally have grave inconveniences, he decided upon replacing the liquid, as the latter was being withdrawn by a body much less injurious—that is, by sterilized air; and it was thus that, after four punctures practised in the space of five months, he was able to cure this patient, not only of his pneumothorax and of his pleuritic effusion, but also of his tuberculosis. This was proved by the sputa and the pleuritic fluid, which at first contained numerous tuberculous bacilli, but from which they were now perfectly free. The learned professor exhibited the phials and the divers instruments which constitute the technique of the operation. He then described the *modus agendi* and the divers phases of the principal operation, and of the successive operations. He applied the same treatment to two other patients affected with pneumothorax of tuberculous origin, and with equal success.

The following is a summary of the conclusions arrived at by the author: 1. It is possible completely to evacuate the liquid of pleuritic effusions consecutive to pneumothorax, on the condition of substituting for it sterilized air. 2. By being disengaged of all germs by its filtration through cotton, the air is deprived of injurious action, and does not provoke any alteration of the pleuritic liquids. 3. This practice suppresses the grave dangers which result from the presence of a large quantity of liquid in the pleural cavity, or from the rapid evacuation of a great effusion. 4. It permits, on the other hand, the avoidance of serious inconveniences, and of frequently renewed punctures, and saves the lungs from the possibility of a slow and progressive distention. 5. Finally, by leaving for a long time the lungs of a patient in repose and inactivity, the cicatrization and the definitive cure of the tuberculous lesions are promoted.—*Lancet*, June 2, 1888.

Experimental Researches on Tuberculosis.—Dr. Cornet publishes in the *Internationale Klinische Rundschau* an account of a series of experimental investigations on tuberculosis which he has been conducting for the last two years in the Berlin Hygienic Institute. The experiments were divided into three groups: the first of these dealing with the air and dust in dwelling-houses, hospitals, etc.; the second group comprising observations directed to the parts of the body affected by tubercle artificially introduced in different situations; and the third group consisting of attempts to solve the problem of the possibility of rendering the tissues unsuitable as a cultivating medium for tubercle bacilli. In order to examine the walls and floors of rooms the surfaces were washed over with sterilized sponges, which were then used to inoculate broth, the resulting culture being injected into the abdominal walls of three guinea-pigs. The animals (if they did not die of some intercurrent affection) were killed forty days later, and a careful necropsy made. Twenty-one hospital wards, in which most of the patients were phthisical, were examined in this way, the result being that from the dust of fifteen of them tuberculosis was set up. Similar observations made in lunatic asylums showed that the walls of these establishments are very frequently infected with the tubercle. Private houses where persons affected with phthisis had lived gave likewise very distinct positive results; out-patient departments and surgical wards appeared, on the other hand, to harbor no tubercle. One important observation made was that where phthisical people had been in the habit of expectorating on the floor, this was certain to yield infectious cultures, whereas in cases where handkerchiefs or spittoons had always been used the liability of the dust to prove infectious was very greatly diminished.

Regarding the organs affected, Dr. Cornet fully confirms Koch's observation that, except the actual point of introduction, the organs most affected are the nearest lymphatic glands; thus, when inhalation is the mode of infection adopted, the bronchial glands are the organs most affected; when injections are made into the abdominal walls, the inguinal glands of the side selected show the greatest degree of tuberculous infection; and when the virus is introduced directly into the abdominal cavity, the omentum is the part most affected.

The therapeutical observations were made with tannin, "pinguin," sulphuretted hydrogen water, menthol, corrosive sublimate, creoline and creasote, all of which were given in much larger doses in relation to the body weight than anyone would think of prescribing for human beings. In the case of corrosive sublimate toxic symptoms were induced before the tubercle was injected, and care was taken with all the other remedies that the system was well saturated with them. Notwithstanding all this, however, every animal died, not the slightest hindrance being apparently caused to the development of the tubercle bacilli by any of the remedies. Dr. Cornet remarks that, of course, the results of experiments on guinea-pigs must not be taken as necessarily holding good for human subjects, as he has himself repeatedly proved the great value of creasote in the treatment of phthisis. Again, some infected guinea-pigs were sent to Davos, others being kept in Berlin, the conditions of life of the two sets of animals being rendered as similar as possible. All of them died in about the same time, and no perceptible difference was found in the degree of tuberculous infection of the tissues in the two classes of cases. Dr. Cornet promises to publish the details of all his observations in the *Zeitschrift für Hygiene*.—*Lancet*, May 19, 1888.

An Antiseptic Paste.—*L'Union Médicale* of May 19th, 1888, gives the following formula for an antiseptic paste:

Iodoform.	gr. 40.
Essen. eucalypti	ʒ 5.
Paraffin.	ʒ 12½.
Vaselin.	ʒ 12½.

This paste is especially adapted to the treatment of ulcers.

Sulphonal.—Mr. Ernest Lovegrove states that the effects of sulphonal upon patients is very discouraging. He finds that for several hours after taking the drug no appreciable effect could be observed, but during the greater part of the following day there was extreme drowsiness, also considerable cyanosis. The best mode of administering sulphonal is to mix it with pulv. tragacanth co. and water.—*British Medical Journal*, May 26, 1888.

Dilatation of the Stomach in Diseases calling for Surgical Treatment.—Bazy, in the *Gazette Hebdomadaire* of May 18, 1888, writes that a dilated stomach furnishes a good

lodging for septic germs, which may give rise to constitutional infection after operations. He advises the diagnosis of dilated stomach before operation, and the use of proper gastro-intestinal disinfectants.

The Treatment of Diseases of the Stomach.—DR. P. C. KNAPP, in an instructive article in the *Boston Med. and Surg. Journal* of June 7, 1888, reviews the recent advances in the diagnosis of gastric disease, especially as regards the presence or absence of free hydrochloric acid in the gastric juice. These new methods, he claims, will alter our present method of treatment. In the majority of cases there is a normal or excessive amount of hydrochloric acid; hence the common exhibition of it is needless and often injurious. Where the acid is in excess we should not depend on alkalies. The stomach should be washed out at night, Carlsbad water given in the morning, and the stomach given increased work by giving the patient an albuminous diet, avoiding carbohydrates. When acid is absent, or much diminished, the ordinary dose (ɱv–x) is much too small. Ewald (*Berlin. klin. Wochenschr.*, Nos. 3, 4, 1886) has calculated that to render neutral juice properly acid, thirty to forty minims should be given after each meal, in three doses fifteen minutes apart, beginning about an hour after meals. When acidity of the stomach is due to lactic acid, from fermentation, this should not be combated solely by alkalies, although Carlsbad may be used. The stomach should be washed out, and hydrochloric acid given, for it will be remembered that when hydrochloric acid is formed during digestion it checks the formation of lactic acid. In catarrh and dilatation, washing out of the stomach is a remedy to be first employed. In muscular insufficiency, strychnine and very mild faradic currents may prove serviceable. In "nervous dyspepsia," as Knapp long believed, special treatment is uncalled for; we must build up the nervous system, and the stomach will take care of itself.

He said nothing of that panacea for all disturbances of digestion, of which at least nineteen varieties are brought to our attention weekly, namely, pepsin. He always acted on the statements which physiologists have been making for years, that pepsin is required for digestion only in small amounts, and that hydrochloric acid is the important factor. In the great majority of cases there is plenty of pepsin in the gastric juice, and the addition of any more is needless, and, therefore, wrong. In a few instances, where partly digested food is to be given, pepsin becomes necessary in its preparation, otherwise the use of pepsin is thoroughly unscientific.

Saline Purgatives in the Treatment of Typhlitis and Peritonitis.—DR. C. W. SUCKLING, in the *British Medical Journal* of May 26, 1888, states that in typhlitis due to fecal retention, and in peritonitis from the same cause, saline purgatives are of great value, especially if enemata fail to act. In moderate doses they do not cause peristalsis, their action is quite painless, and they are exceedingly useful in washing away hardened scybala. During their administration the abdomen should be frequently examined, and any accumulation of fluid in the intestines treated by stimulants.

In a case which he narrates, the saline aperient evidently had caused a large flow of fluid into the intestine, but the bowel was not sufficiently powerful to evacuate it; restoration of tone by stimulants at once enabled the bowel to empty itself.

Injections of Ozone Water in Cancer.—SCHMIDT reports two cases of cancer treated by parenchymatous injection of ozone water in varying proportions. From one to ten injections daily were given, varying with the size of the cancer. No great pain was caused by the injection, and improvement in the condition of the tumors followed. Microscopic examination showed a diminished number of nests of cancer cells. The cases improved rapidly, and the formation of normal connective tissue occurred. No ill effects followed the treatment.—*Wiener medizinische Presse*, No. 19, 1888.

Extirpation of the Gall-bladder.—CREDÉ (*Korresp.-Bl. der ärztl. Kreis-u Bez.-Ver. in Sachsen*, 1888) relates a case of complete extirpation of the gall-bladder for lithiasis and hydrops. The patient, a female, aged twenty-nine years, had suffered with hepatic colic at eighteen, with peritonitis, presumably from the existence of gall-stones, at twenty. In the summer of 1886, she noticed, to the right of the umbilicus, a small, painful tumor, which by February, 1887, had grown to the size of a hen's egg. On the 23d of November, 1887, the abdomen was opened, the gall-bladder, containing five ounces of a cloudy, viscid fluid and forty calculi, with difficulty separated from the liver, and removed; a double ligature being applied to the cystic duct close to the common duct. The patient was out of bed early in January, 1888. She has since been well, has gained flesh and attended to her household duties. Following an attack of vomiting, thirty-six hours after the operation, severe pain was felt at the site of the operation wound. Fever and tenderness set in, and, on the fifth day, the wound was reopened at its middle, and some pus and blood-clots evacuated. This illustrates the danger of secondary hemorrhage from the liver, to control which we are almost powerless. On this account, in the case of anæmic individuals, incision into the gall-bladder, without extirpation, commends itself, but with ligature of the cystic duct. In the case of patients with some degree of resistance, however, the speaker considered complete extirpation indicated as the best method, as leading to the most rapid recovery without leaving fistulæ behind. Of course, operations upon the gall-bladder are not to be performed in all cases of disease of the organ. In most, nature is able to help herself; but there will always be certain cases in which danger to life arises and persists, and operative treatment must be instituted; and it may be said with satisfaction that the methods of operation have already been so far perfected that patients may submit to surgical measures with a prospect of pretty certain success.—*Memorabilien*, May 31, 1888.

The Painless Extraction of Teeth.—To extract teeth without pain, HÉNOQUE and FRÈDET (as reported before the Société de Biologie, at Paris, on February 4th) apply the ether spray to the neighborhood of the external auditory meatus. The anæsthesia affects the branches of the trigeminus on the face and suffices for the purpose. The procedure is simple and harmless.—*Memorabilien*, May 31, 1888; from *Zeitschrift für Therapie, etc.*, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 7, 1888.

THE HEART IN LOCOMOTOR ATAXIA.

BERGER and ROSENBACH, in 1879, called the attention of the profession, in a brief notice in the *Berliner klinische Wochenschrift*, to the association of aortic insufficiency with locomotor ataxia. They published notes of seven cases without comment. In the following year, ANGEL, in an article in the same journal, entitled "The Coincidence of Heart Lesions with Tabes," reported, in a series of twelve patients suffering from locomotor ataxia, five cases in which there was the sign of aortic insufficiency, namely, a diastolic murmur, present only however after muscular effort, and disappearing during prolonged rest. The murmur was not heard at all in the morning while the patients still remained in bed. This observer regarded the murmur in question as due to abnormal action of the heart-muscle.

GROEDEL, whose opportunities for the study of locomotor ataxia at Bad-Nauheim have been very extensive, regards the occurrence of cardiac affections in this disease as wholly accidental (*Deutsche medicinische Wochenschrift*, May 17, 1888). In this view he concurs with Eulenburg and Erb.

Between 1875 and 1879—namely, at a time when his attention had not yet been especially called to the subject—Groedel noted, in forty-three cases of locomotor ataxia, only two in which the signs of valvular disease were present. The records of this period refer either to absence of heart complications in the other forty-one cases, or to the occasional occurrence of quickening of the pulse rate and precardial distress and oppression. Between 1880 and the close of 1887, a period during which every case of locomotor ataxia was studied with especial reference to the condition of the heart, valvular lesions were detected in only four out of one hundred and eight cases, and in no instance was he able to recognize the murmur of aortic insufficiency after muscular exertion, as described by Angel.

Cardiac phenomena of a different kind were, however, very frequently observed. These consisted of feeble action of the heart, increased frequency of the contractions, small pulse, faintness of the sounds—manifestations not only common in enfeebled subjects but also in those still well-nourished and strong. The patients presenting these signs frequently complained of palpitation, shortness of breath on exertion, even of occasional attacks of palpitation while at rest and after excitement. In only two instances were these symptoms associated with the signs of dilatation of the right and left chambers of the heart. He concludes that even these symptoms are in no wise characteristic of locomotor ataxia, since they occur in all kinds of chronic maladies associated, as is so commonly the case, with anæmia and neurasthenia. Leyden has noted four cases, and Vulpian one case of locomotor ataxia in which peculiar paroxysmal attacks closely resembling angina pectoris occurred.

Groedel, following Leyden, regards these attacks of paroxysmal precordial anguish and oppression, of which he communicates the notes of two interesting cases, as probably of the nature of irregularly developed girdle pains, or, at least, as neuralgia in the distribution of the cardiac branches of the vagus, as the gastric crises and the laryngeal and bronchial crises are to be referred to the corresponding branches of the vagus.

ANOTHER STEP IN ADVANCE.

IN our issue of June 16th, the hope was expressed that other leading medical colleges would soon follow the example of Jefferson in extending the curriculum to three obligatory winter sessions. The College of Physicians and Surgeons, of New York, now publishes a similar announcement. The profession and, more especially, the Alumni of the remaining prominent medical colleges have reason to expect that these schools will now make haste to align themselves with other institutions of the first class. The plea of "financial suicide" will no longer avail in extenuation of further delay. Loss of prestige will, in the end, surely entail the money losses they

wish to avoid. If these chief competitors make the move together, they preserve their present business relations to each other, while they give a much needed lift to the standard of medical education throughout the country. The really meritorious colleges everywhere will see at last that their interests lie in the direction of their inclinations. For, surely, no faithful teacher will deny that he wants to extend the period of study, in order that he may fairly exact higher qualifications from the candidate for the medical degree.

A NEW medical school, under the auspices of the Roman Catholic Church, is projected at Brooklyn, Bishop Loughlin being president of its board of trustees. It will be connected with the St. Mary's Hospital and under the care of the Sisters of Charity, but otherwise will be non-sectarian in its management. According to an Act of the last Legislature, the Faculty of this proposed college will be empowered to grant the usual medical degrees and licenses to practise.

AT the last meeting of the British Columbia Medical Council, it was decided to proceed vigorously against unregistered and unqualified practitioners. In pursuance of this policy, a Dr. Millar, an English physician, was, on the 14th inst., brought before the police court at Vancouver, British Columbia, charged with practising his profession in that province without having obtained a license from the Medical Council. Mr. Walker, barrister, of Victoria, B. C., conducted the prosecution on behalf of the Medical Council of British Columbia, and the defendant was fined twenty-five dollars and costs.

It is the intention of the Medical Council to proceed against all parties practising medicine in the province without a license.

THE coming meeting of the British Medical Association at Glasgow, in August, bids fair to be crowned with marked success. The announcements in the English journals of the untiring efforts of all the various committees promise a programme of instruction and entertainment that should crowd the week to overflowing. There is an International Exhibition in successful operation in that city, which will absorb many of the spare half hours of the delegates, and ten different excursions for the closing Saturday have been planned for strangers who wish to get a glimpse of the firths, lochs and hills of romantic mid-Scotland. In the Sanitary Section, the admirable progress made by the Scotch cities in ambulance work will be illustrated by a fine array of wagons and appliances for both military and civil practice.

THE Société de Biologie, of Paris, at its meeting on June 9th, on the suggestion of Brown-Séquard, resolved to convene an International Physiological Congress next year, at Paris. Brown-Séquard, as chairman, Richet, d'Arsonval and Marey were appointed a committee to make the necessary arrangements.

A SILVER medal was awarded at Amsterdam to Prof. Adamkiewicz, for his investigations upon peptone.

THE Dutch Scientific Society, of Harlem, has awarded Prof. Virchow the Boerhave Medal for Anthropology.

THE prospectus of the new serial issue of clinical lectures, entitled *Berliner Klinik*, to be edited by Fürbringer and Hahn, announces that the opening numbers will consist of two lectures by Professor Senator, upon "The Methods and Aims of Medical Activity," and upon "Icterus, its Origin and Treatment."

PROF. DONDERS has directed that the memorial fund of 57,000 marks ($14,250), collected by his friends and admirers on the occasion of the anniversary of his seventieth birthday, be devoted to affording means for promising students of the University of Utrecht to continue their studies in ophthalmology and physiology.

THE *British Medical Journal* of June 23d, in commenting on the late Emperor's case, says, "We understand that the illustrious patient had thoroughly made up his mind not to submit to any operation that might shorten his life or destroy his voice. This decision was altogether independent of medical advice, though it was afterward strengthened, as was natural, by the negative results of Sir Morell Mackenzie's clinical and Prof. Virchow's pathological examinations."

THE watchful tendance over a person bent on suicide can be intermitted never. It is related of the wife of a prominent pharmacist of Chicago that she was subject to frequent fits of melancholia that necessitated constant watchfulness, and the removal of all weapons or dangerous articles. The patient was, however, able for a brief period to elude the

eye of her attendant, and immediately took the opportunity to pour oil over her clothing and person, and to set fire to herself, and by this ingenious and horrible expedient put an end to her mental sufferings. For cunning and fortitude, this case will stand as a notable example of the lengths to which those persons whose minds are rendered desperate by depressing emotions will go.

The friends and pupils of Dr. George Johnson have just presented him with his portrait by Mr. Holl, on the occasion of his retirement from the professorship of Clinical Medicine, after forty-five years service at King's College and King's College Hospital.

The first report of the work done at the Margaret Williamson Hospital, an American missionary undertaking for the treatment of Chinese women and children, has been published at Shanghai, by Dr. Elizabeth Reifsnyder, Physician-in-charge. It is a well-printed pamphlet of twenty pages, and gives a creditable showing of the relief furnished in the two years ending December 31, 1887: 54,000 patients were received at the Dispensary, and about the same number of prescriptions issued. The Hospital is closed in August and September of each year. The report states that there is already need for larger accommodations and more help; on one very busy day, there were fifty patients turned away. This institution is truly a bright spot in a benighted region.

We regret to read the announcement by a cablegram from London, dated June 28th, of the death of Dr. J. Milner Fothergill, a medical author well known on both continents. It is less than twenty years ago that he first appeared in print; in 1870, he took the Hastings Prize of the British Medical Association. Several of his writings have been reproduced in this country, in the case of one of his books, even to its third edition, and he was a frequent contributor of letters and papers to our American journals.

Dr. Benjamin King, one of the oldest officers on the retired list of the army, died June 24th, in his ninety-second year. He was graduated from West Point in 1807 and served in the war of 1812. He acted as surgeon in the Seminole war and in the Mexican war. He was put upon the retired list about twenty-seven years ago.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section in Pædiatrics.

Stated Meeting, June 27, 1888.

The Chairman, J. Lewis Smith, M.D., Presiding.

Dr. A. Jacobi made some

REMARKS ON SUMMER COMPLAINT,

with special reference to their etiology.

Dr. A. V. Meigs, of Philadelphia, then read a paper on

THE DIETETIC MANAGEMENT OF THE SUMMER DIARRHŒA OF INFANTS.

(See page 4.)

Dr. S. Baruch then presented a

CLINICAL STUDY OF THE ETIOLOGY AND TREATMENT OF SUMMER DIARRHŒA OF INFANTS.

(See page 8.)

Dr. George B. Fowler then reported some

EXPERIMENTS WITH DIFFERENT SPECIMENS OF PEPSIN.

No pure pepsin is in use, he said. The various specimens in the market are prepared from the mucous membrane of the hog's stomach, with varying degrees of care and varying results as to purity. The mucous membrane is first scraped, and, with the pepsin, the mucus of the glands is also removed. A glycerin extract is then made, the pepsin is precipitated, but, as it precipitates, the mucus precipitates also. New extracts are then made, and new precipitates formed; and, finally, the extract is dried, the product being commercial pepsin.

In the experiments which were made, thirteen different specimens, by as many manufacturers, were taken, one grain of each being used for the test. Each specimen was placed in a ten ounce bottle, which also contained eight ounces of a one-half per cent. solution of hydrochloric acid, and twelve hundred grains of egg albumen, which was to be digested. Each bottle was kept at a temperature of 100° F., for six hours, being agitated every half hour, and then allowed to cool. An additional bottle containing the same quantity of albumen and acidulated water, but no pepsin, was placed by the side of the others, for the purpose of comparison with those in which digestion was being accomplished. The results varied greatly. All the albumen was digested, and a clear solution obtained by the pepsin of Parke, Davis & Co. That of Fairchild Bros. & Foster and that of Hawley, were nearly as good. Most of the other specimens showed very weak digestive properties.

Another series of experiments was also made with various medicinal agents, to ascertain the extent to which they operated as inhibitors of digestion, the medicinal substances being placed in bottles similar to those previously described, and containing the same quantity of pepsin, egg albumen and acidulated water.

Salicylate of soda, in twenty grain portions, stopped digestion, apparently fixing the hydrochloric acid. After six hours, digestion had not begun. When portions of three grains were used, digestion was retarded two hours.

Portions of twenty grains of sulphate of quinine stop-

ped digestion, no change having taken place after six hours. When five grains were used, digestion was retarded; when three grains were used, no retarding effect was apparent. Mariani wine also inhibited digestion; half ounce portions caused a chocolate-colored precipitate, no digestive action being apparent.

Acetate of lead, in two grain portions, had no apparent inhibitory effect. Tincture of the chloride of iron, in thirty drop portions, inhibited digestion, its astringent action upon the albumen being very apparent.

Salol, in ten grain portions, caused slight delay in digestive action.

Antifebrin and antipyrin had no apparent inhibitory effect, the same being true of bichloride of mercury and calomel.

Chalk mixture, tincture of kino and tincture of catechu all showed their astringent action, and either delayed or entirely prevented digestion. Resorcin had no inhibitory effect. Prepared chalk, in portions of twenty grains, combined with the albumen mechanically, and no digestion took place.

Dr. Caillé responded to Dr. Baruch's statement that the plan which he (Caillé) had proposed for sterilizing milk would not accomplish it. Dr. Caillé had not intended that the term should be used in an exact sense, but only that the method suggested sterilized the milk relatively to raw milk. He thought the conclusions of chemists and bacteriologists, in regard to such diseases as *summer complaint* and the action of foods and drugs, were unsatisfactory, and that we could arrive at trustworthy conclusions for clinical purposes only by means of collective investigation. This would enable us to find out why some children thrive on certain kinds of food, and others do not.

Dr. Hanwood expressed surprise that, in the papers which had referred to feeding, nothing had been said about condensed milk, which, by its mode of preparation and its abundance of sugar, offers great advantages as a food for infants. He had, to his satisfaction, investigated the method by which it was prepared and, in practice, he found it more useful than any other form of food.

Dr. A. Jacobi adhered to the opinion which he had expressed in his writings, that condensed milk is not a good food for infants. With reference to the experiments of Dr. Fowler, he was not convinced that tincture of iron is not useful in the treatment of *summer complaint*. One never gave it in thirty drop doses, and it had usually been found efficient and not harmful to the digestive function, when given in small doses. Of course, the administration should be stopped when the stomach became rebellious. It should be remembered that carbonate of lime neutralizes whatever it combines with, and thus delays digestion. This should teach us that alkalies (with, perhaps, the exception of bicarbonate of soda) should not be given after, but before eating. Their action then will be very beneficial, for they will neutralize the harmful fatty acids which are in the stomach at that time, and prepare the organ for the proper performance of digestion.

Dr. Meigs did not agree with Dr. Baruch, that diarrhœa in hand-fed children is rare in winter. Infants with diarrhœa frequently come into the hospitals in the winter-time and die from it. With others, it begins in the hospital, and is alike fatal. It is true that these children were badly nourished and predisposed to diseases of such a character. He thought the consensus of opinion now is that if cow's milk be used as an infant food it should be diluted, and that cream and milk sugar should be added. This makes it quite similar to to woman's milk, which must be the standard.

Dr. Baruch objected strongly to the use of condensed milk, believing it to be one of the most pernicious forms of food which are given to children.

THE ONTARIO MEDICAL ASSOCIATION.

The Eighth Annual Meeting, held at Toronto, June 13 and 14, 1888.

(Specially reported for The Medical News.)

(Con inued from page 720)

Thursday, June 14th.

Dr. Hunt, of Clarksburg, reported a case of

IDIOPATHIC GLOSSITIS,

the only one he had met in twenty years' practice. The patient was a farmer, aged thirty-five years. The tongue swelled so as to fill the mouth and protrude from it. He was in this condition when Dr. Hunt first saw him. Free incisions were made into the tongue, with much relief. Next day there was again great distress and dyspnœa, and laryngotomy was resorted to, quite relieving the difficulty of breathing. He improved rapidly and the tube was removed. Three days after the laryngotomy his bedroom was scrubbed, and he returned to it while the floor was still wet. He soon began to suffer from dyspnœa, and he was almost moribund, six hours later, when Dr. Hunt saw him. The tube was reinserted, but it was too late; death took place immediately.

Dr. C. M. Smith, of Orangeville, read a paper on

THE TREATMENT OF COMPOUND FRACTURE OF THE LOWER THIRD OF HUMERUS — A NEW APPLICATION OF SAYRE'S SHORT-HIP-SPLINT.

He showed the modified splint and its application on a patient he presented, in whom there had been a severe compound fracture of the lower end of the humerus. The result was eminently satisfactory, though for a time it was doubtful if the arm could be saved.

Dr. William Gardner, of Montreal, read a paper on

RUPTURED TUBAL FŒTATION CYSTS,

and related a case. The patient, aged twenty-nine, was married in July, 1887, and had an ordinary miscarriage in the following October. From this she recovered easily. Menses appeared normally on the 2d December. Patient remained well during the rest of the month, except for some of the signs of pregnancy slightly marked. Early in January a slight bloody discharge appeared, lasting two weeks. It was unlike menstrual blood. About the middle of January she was seized with intense pelvic pain and collapse, which lasted two days. During this period Dr. Browne, her medical attendant, feared that she would die, but she slowly rallied and made a partial recovery, but at the end of a fortnight later, early in February, there were alarming recurrences of pain and other symptoms. Dr. Gardner was then asked to see the patient, Dr. Browne stating that he believed the case to be one of extrauterine gestation. The patient was found to be suffering from severe pelvic and abdominal

pain, with great distention. The pain was not controlled by full doses of morphia; vomiting was frequent; the pulse weak and rapid. Vaginal examination revealed a free bloody discharge; fixation, softening and increase of bulk of the uterus, and to the right and behind it a firm, painful swelling. The use of electricity was precluded by the evident hemorrhage and peritonitis.

The abdominal cavity was opened, and a quantity of blood-clot of varying age and bloody serum removed. A ragged, friable, granular mass, an expansion of the right Fallopian tube, was torn away in attempting to raise it to the edge of the wound to apply the ligature. No ligature was applied. The abdomen and pelvic cavity were washed out and drained. When put to bed the condition of the patient was alarming, the pulse was 140 and very weak. She steadily rallied and made a complete though tedious recovery, the tediousness being due to cystitis. On examining the substance removed, a blood-stained fœtus about one inch in length was discovered, as well as ample evidence of chorial villi. The fœtus had evidently been dead for some time, probably from the date of the first urgent symptoms, the state of things indicating clearly that electricity would have been of no use at any time after the patient had called in her doctor.

Dr. Gardner remarked on the difficulty of diagnosis, which probably, however, is not so great as often imagined, and not greater than in some cases of uterine pregnancy. Having made a diagnosis of extrauterine pregnancy—as the great majority of the cases are tubal—the question of treatment arises. Practically this may be considered under three heads. Fœticide by electricity, abdominal section to remove the fœtation cyst and expectancy. There is much difference of opinion on the question of treatment at the present time.

Electricity.—The faradic current is to be selected. It is simple and easy to apply, and the apparatus almost always at hand. Its use is opposed *in toto* by some eminent abdominal surgeons, yet there is a mass of evidence in its favor so large that its position seems unassailable. The author has published a successful case (*Canada Med. and Surg. Journ.*, August, 1885), in which the evidences of correct diagnosis and cure were as complete as anything could be, short of seeing the fœtus or chorial villi.

Mr. Lawson Tait, Dr. Imlach, Dr. Johnston, Dr. Janvrin and others say that as soon as the diagnosis is made we must open the abdomen. In support, they say that it is very rare that the diagnosis is made until pain and collapse supervene, which, they say, indicate rupture, and not merely contraction or distention of the tube, as believed by the advocates of electricity.

Unfortunately, and this is the strong point of the case for the advocates of immediate section, the first symptoms demanding medical aid may be those of the fatal rupture, and, as Dr. Herman says, if we judge of the fatality of extrauterine pregnancy by the results of abdominal section and post-mortems, we must regard it as being great; but there is no doubt that extrauterine fœtation is far more common than is generally supposed, and that rupture with hemorrhage, and escape of the fœtus into the peritoneal cavity, often occurs, and is recovered from by absorption of both blood and fœtus. There are clinical facts in plenty to prove this. The fact, however, remains that whenever the diagnosis is made, and when the symptoms are serious, and whenever there are serious symptoms of a doubtful character, this grand life-saving operation must be done to enable us to deal as best may be the case with the condition found.

The author's case goes to prove that even after there is every evidence of the death of the fœtus by electricity, symptoms may subsequently arise to render necessary abdominal section. It may be premised that the earlier the stage of pregnancy at which fœticide is effected, the less likely are after-symptoms to arise.

Expectancy.—Presuming the case to occur in thoroughly experienced and competent hands, the diagnosis to have been made, and the symptoms severe, an expectant treatment must be condemned. It will be proper only in doubtful cases with mild symptoms.

DR. SAMUEL CLARK, of Toronto, read a paper on

NEURASTHENIA.

He divided neurasthenics into three classes: 1st. Those who were physically in good health, but mentally unbalanced, although not insane. 2d. Those who were anæmic, and, consequently, weak in body. 3d. Those who were afflicted with such neurosis as lead to or evoke this disorder.

Dr. Clark strongly deprecated the use of narcotics, except in very extreme cases. Three hours of natural sleep had more recuperative power in them than could nine hours of drugged quietude. The principal medicines he used were such as the arsenites, phosphide of zinc, nux vomica, pyrophosphate of iron, cod-liver oil and the like.

(*To be concluded.*)

CORRESPONDENCE.

THE EXTERNAL USE OF SULPHUR IN SCIATICA.

To the Editor of THE MEDICAL NEWS,

SIR: In the May number of *The American Journal of the Medical Sciences*, page 109, I notice a recommendation, from the *Revue de Thérapeutique*, of the external use of sulphur as a remedy for sciatica, which is spoken of as an "extraordinary statement," etc., leaving the impression on the reader that you consider the external use of sulphur in sciatica as something original with Drs. Mussy and Duchesne.

The external use of sulphur in powder for sciatica is an old, popular English remedy. Fuller, in his well-known classic work on *Rheumatism, Rheumatic Gout and Sciatica*, third edition, page 472, says: "Nothing, however, proves more generally efficacious than sulphur, applied externally. Whatever its mode of operation, the fact remains that, employed in this manner, it often subdues pain which has persisted in spite of all other remedies. In many parts of England, the sulphur ointment of the Pharmacopœia is a favorite remedy amongst the poor for the cure of rheumatism, and I am indebted to one of my hospital patients for directing my attention to the subject. He was a man, forty-three years of age, who had been afflicted with sciatica in a severe form about five months. He had undergone a long course of medical treatment before he applied at the hospital, but without obtaining the least mitigation of suffering, when a friend induced him to put sulphur in his boots, and otherwise apply the remedy externally. In four days, he was much relieved, and, in less than a fortnight, had recovered

perfectly. Since that time, I have used it in seventeen chronic, non-inflammatory cases; and, in only six, did it fail in giving relief.

"The mode in which I usually employ it is to sprinkle thickly with precipitated sulphur a piece of new flannel, in which the whole of the affected limb is to be encased, from the foot upward. Whatever the precise influence it exerts in sciatica, there cannot be any doubt that its beneficial effects are most strikingly displayed in chronic cases, unattended by any symptoms of inflammation."

Fuller refers to Dr. Nicholson's special treatment with sulphur in the cure of rheumatism in 1820, and to an article by Mr. George Tucker, *Lancet*, March 7, 1835.

I feel like apologizing for troubling you with this unimportant historical matter, but for the fact that sciatica is so frequent, so obstinate, and so painful and distressing to the patient. I never fail to try sulphur in most cases of sciatica and chronic rheumatism which show an obstinacy in yielding to the more commonly used remedies, and I always send my patients with sciatica and chronic rheumatism first to sulphur springs, when sending them to any springs. It has been my custom while using sulphur externally, as advised by Fuller, to administer it freely internally, and, when there is anæmia, to combine it with iron; for instance, my usual formula is

℞.—Sulphur. (præcip.),
Ferri carb. . . . . āā ℥iv.
Glycerini . . . . . ℥iv.
Aquæ gaultheriæ . . . . ad ℥iv.
A teaspoonful every two hours.

I also frequently use this formula in the treatment of the diseases which seem to have a rheumatic tendency, such as diphtheria, scarlet fever, chorea, etc.

W. F. McNutt, M.D.

NEWS ITEMS.

The Clinical History of the Case of the Late German Emperor.—Dr. Morell Mackenzie has published in the *British Medical Journal*, of June 23d, the following clinical history of the late Emperor Frederick's illness. The first definite symptoms of the illness, which, on June 15th, deprived Germany of a truly enlightened ruler and the world of a most noble-hearted man, appear to have shown themselves in January, 1887. There is said to be a somewhat remote history of cancer in the family, and for many years, the late emperor suffered from a certain delicacy of the throat. In 1886, he had an attack of measles, from which he recovered without any bad after-effects, but it was noticed that he never quite regained the high spirits for which he had before been remarkable. In the latter part of the same year, he suffered from a succession of obstinate "colds," which finally culminated in such extreme and persistent hoarseness that his physician in ordinary, Dr. von Wegner, called in Dr. Carl Gerhardt, Professor of Medicine in the University of Berlin, and a recognized authority on diseases of the throat. On laryngoscopic examination, a small growth was seen springing from the left vocal cord and interfering with its action. This was, in great part, destroyed by the electric cautery, and in the spring, the illustrious patient was sent to Ems, where it was hoped that the waters would complete the cure. The symptoms, however, returned with greater severity, and the growth increased in size so rapidly that suspicion of its being malignant was excited.

Professor Ernst von Bergmann, the leading surgeon in Berlin, and, soon afterward, Professor Tobold, one of the pioneers in laryngology, were consulted, and it was agreed that an operation was desirable in order to determine the nature of the disease, and, if possible, extirpate it. With this view, it was proposed to perform thyrotomy in the first place, and, if necessary, to follow this up by such further surgical measures as the circumstances of the case might seem to call for. Before carrying this plan into execution, however, the medical attendants, being fully alive to the vast responsibility of their position, were anxious to have the advice of some laryngoscopic authority whose opinion would command general respect. It was unanimously decided to call in Sir (then Dr.) Morell Mackenzie, who accordingly proceeded to Berlin on May 20th. He found a sessile growth, about the size of a split pea, but oval in shape, situated on the posterior extremity and inner surface of the left vocal cord, the mobility of which was distinctly impaired. There was general congestion of the mucous membrane of the larynx. Dr. Mackenzie did not consider the clinical evidence as to the character of the affection decisive one way or the other, and suggested that, before any further steps were taken, a portion of the growth should be removed through the mouth and examined microscopically. He succeeded in thus extracting two or three fragments, which were at once submitted to Professor Rudolf Virchow. That eminent pathologist having failed to find any trace of malignant structure in them, it was unanimously agreed that Dr. Mackenzie should take the case into his own hands for a time, and should attempt to eradicate the disease, without external operation.

In June, the Emperor (then Crown Prince) came to England, and Dr. Mackenzie removed the remaining portion of the growth. After examination, this was, on July 1st, pronounced by Professor Virchow, to be a "hard, compressed warty growth that has started from a moderately irritated and thickened surface, and the examination of its base has not afforded the least support for the idea of a new formation penetrating inward." The voice was at this time so much improved that, on July 14th, the Prince, in visiting the Throat Hospital, made a little speech to the patients, in which he expressed a hope that they might be cured as quickly as he had been. The larynx, however, remained somewhat irritable, and the whole throat showed a tendency to become congested on very slight provocation.

At the beginning of August, there were signs of recurrence of the growth, and Dr. Mackenzie, on two occasions, applied the electric cautery with the result of destroying it entirely. The Prince then went to the Isle of Wight, the climate of which, however, proved too relaxing, and his throat gave him a good deal of trouble. Dr. Norris Wolfenden, who attended him while there, observed at the back of the larynx a slight thickening of the mucous membrane in the form of a ridge, extending horizontally from the base of one arytenoid cartilage to the other. The action of the vocal cord was still somewhat defective, as it had been in Berlin. The bracing air of Braemar was next tried, and considerable improvement took place in the local condition; the

thickening just mentioned was absorbed, the congestion of the larynx disappeared, and the affected cord moved more freely. Early in September, however, there was a relapse, and on the 18th of that month, while the Prince was at Toblach, in the Tyrol, Mr. Mark Hovell, who had succeeded Dr. Wolfenden, noticed a swelling half an inch below the left cord and parallel with its free border. This increased in size; œdema of the left aryteno-epiglottic fold supervened, and there was some constitutional disturbance. The acute symptoms passed off in a few days, and the Prince proceeded to Italy.

Toward the end of October, active hyperæmia of the whole interior of the larynx came on somewhat suddenly; the swelling under the left cord increased in size and began to ulcerate, and a reddish projection was noticed below the right cord. Early in November, the appearance was so ominous that it was thought expedient to have further advice, and Professor Leopold von Schrötter, of Vienna, Dr. Moritz Schmidt, of Frankfort, and Dr. (now Professor) Hermann Krause were summoned to San Remo. After consultation, the diagnosis of cancer of the larynx was arrived at, and the propriety of a radical operation was discussed. The illustrious patient, having fully considered the question, decided not to submit himself to any procedure involving immediate risk to life, but to take his chance with treatment of a purely palliative kind. From this point onward, the disease made steady progress, with occasional exacerbations of the symptoms, owing to the intercurrent development of inflammatory processes in various parts of the larynx. These, in the early part of this year, became so pronounced as almost entirely to mask the essential disease, and hopes were entertained by some of the physicians that the affection might after all prove to be one of perichondritis depending on chronic laryngitis of exceptional severity.

About the end of January, the glottis began to be encroached on to a serious extent, and, on February 9th, tracheotomy became necessary. Professor von Bergmann was telegraphed for, but, before he could reach San Remo, the dyspnœa became so urgent that the operation was performed by Dr. Bramann in the presence of Sir Morell Mackenzie, Dr. Krause, Dr. Schrader and Mr. Hovell. The Prince did not rally from the effects of the operation for some time, and it became clear that the general health was beginning to give way. It was feared that secondary formations had developed in the lungs; but Professor Küssmaul, who was summoned, could find no evidence of such a complication. Soon afterward, however, Professor Waldeyer, to whom, in the absence of Professor Virchow, the microscopical examination of the expectorated matters had been entrusted, pronounced the laryngeal affection to be cancerous. The tracheotomy wound was for a few days in a very unhealthy state, and there was a good deal of suppuration. Great difficulty was experienced in finding a tube to fit comfortably in the wound, and finally Sir Morell Mackenzie was obliged to fashion one with his own hands. The illustrious patient thereupon recovered his appetite, and was able to sleep; and he regained his strength to such a degree that when his father, the Emperor William, died on March 9th, he insisted on returning at once to Germany, although the weather was most inclement.

At Charlottenburg, the new Emperor was able, for a time, to discharge many of the duties of his exalted position, and he threw himself into the conduct of State affairs with such energy that his physicians were anxious to get him away from the neighborhood of Berlin. On April 13th, the tracheotomy tube became partially blocked by a mass projecting into its lower end, and some difficulty occurred in replacing it by a longer one. There was a good deal of hemorrhage, the blood finding its way into the lungs and setting up bronchitis. Diffuse suppurative inflammation of the loose tissue surrounding the trachea ensued, and for some days there was considerable pyrexia with occasional rigors. Apprehensions were felt that pyæmia was setting in, but the general condition improved on the establishment of a profuse purulent discharge which continued more or less till the end. In May, the inflammatory element in the case underwent a notable abatement, and there was a pause in the progress of the disease for two or three weeks. At this time, Professor Virchow again examined some of the discharge, without finding in it anything that, to his mind, was a proof of cancer.

On June 8th, it was obvious that a fresh complication had occurred; difficulty of swallowing came on, and it was thought that perforation into the œsophagus had taken place. On June 9th, Trendelenburg's tampon canula was substituted for the ordinary tracheotomy tube, with the view of preventing the food from escaping into the air-passage. The Emperor meanwhile was losing ground very fast, and, on the 13th, Sir Morell Mackenzie had to feed him with the œsophageal tube. On the evening of the 14th, pneumonia rapidly supervened, and death took place on the forenoon of the 15th.

The *post-mortem* examination, which was made on June 16th, by Professor Virchow and Dr. Langerhans, in the presence of Sir M. Mackenzie, Drs. von Wegner, von Bardeleben, von Bergmann, Waldeyer and Bramann, and Mr. Hovell, proved that the disease was cancer, complicated by suppurative inflammation of such intensity that the whole structure of the larynx was destroyed, its place being taken by a large abscess-cavity. Although a summary of the results of the *post-mortem* examination has already appeared in the daily newspapers, we regret that we are unable to give the full report, as orders were issued at the last moment that it should not be published.

Before the necropsy was made, Sir Morell Mackenzie, at the request of Prince Bismark, drew up the following report of the case, which he presented to the new Emperor, and which was deposited among the State archives:

"In my opinion, the disease from which the Emperor died was cancer. The morbid process probably commenced in the deepest tissues of the cartilaginous structures of the larynx, and they became affected at a very early date. A small growth, which was present when I first examined the late Emperor, was removed by me by several operations ,and all the portions taken away were submitted to Professor Virchow. He was unable to detect in them any evidence of the existence of cancer. Examinations made, at the beginning of March, by Professor Waldeyer, however, led to the belief that cancer was then present. Whether the disease was originally cancerous or assumed a malignant character some months after its first appearance it is impossible to state. The fact that perichronditis and caries of the cartilages played an active and important part in the development

of the disease no doubt largely contributed to make it impossible to form a decided opinion as to its nature till quite a recent date."

"MORELL MACKENZIE."

The National Association of Railway Surgeons met in convention, in Chicago, last Thursday. An election of officers resulted as follows:

President.—John W. Jackson. M.D., of Kansas City.

First Vice-President.—Dr. Murphy, of St. Paul.

Second Vice-President.—J. B. Murdock, M.D., of Pittsburg.

Third Vice-President.—A. W. Reidnour, M.D., of Massillon, Ohio.

Fourth Vice-President.—B. L. Hover, M.D., of Rochester.

Secretary.—C. B. Stemen, M.D., of Fort Wayne.

Assistant Secretary.—J. H. Tressel, M.D., of Alliance, Ohio.

Corresponding Secretary.—E. R. Lewis, M.D.

Treasurer.—J. Harvey Reed, M.D., of Mansfield, Ohio.

In Memory of Prof. Bodley.—At a meeting of the Faculty of the Woman's Medical College, held June 20, 1888, the following action was taken on the death of Prof. Bodley.

Whereas, our honored Dean and Prof. of Chemistry, Rachel L. Bodley, has been suddenly removed by the hand of death from the arena of earthly activities, in so many of which she was deeply interested;

Resolved, that we, her colleagues in the Faculty of the Woman's Medical College, of Pennsylvania, recognize, in the removal of our senior member, the loss of one most familiar with the historical and traditional features of our College and its past work.

She was thoroughly acquainted with the ardous duties of Dean, which she performed most ably and acceptably, and in which her wise administration secured for the college friends whensoever her influence was exerted.

She was keenly alive to the personal as well as educational requirements of the students, so many of whom, coming as strangers from far distant lands, found in her a friend earnestly solicitous for all that concerned their welfare, and ever ready to do all in her power to further their interest.

She was an able teacher of chemistry, striving successfully by word and illustration to elucidate the intricate problems of her branch.

Religiously devout, she at once placed before those with whom she came in contact a high standard, socially and morally, and did much to establish the same for the college, to the service of which her efforts and indeed her lips were so unsparingly, unceasingly and ungrudgingly devoted.

Possessed of an acquaintance among people in all lands, through her college relations and affiliations, her usefulness to us and to the world can scarcely be overestimated, so varied and extensive had it become.

As a friend, she was genial, kindly, courteous ever, and we shall greatly miss her quiet dignity in our Faculty meetings. In the entire round of college work, with the extensive ramifications of which she was so thoroughly familiar, we feel her loss to be almost irreparable.

Resolved, That these resolutions be transcribed in full upon our book of minutes, and a copy sent to her aged mother.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 26 TO JULY 2, 1888.

BAXTER, J. H., *Colonel and Chief Medical Purveyor.*—Will proceed to New York City on public business connected with the Medical Department, and on completion thereof will return to his station in Washington City.—*S. O. 150, A. G. O.*, June 29, 1888.

OWEN, WILLIAM O., JR., *Captain and Assistant Surgeon.*—Ordered to Fort Leavenworth, Kansas, for duty.—*S. O. 148, A. G. O.*, June 27, 1888.

WOODHULL, A. A., *Captain and Surgeon.*—Granted leave of absence for three months, to take effect about July 10, 1888.—*S. O. 148, A. G. O.*, June 27, 1888.

So much of par. 3, S. O. 142, A. G. O., June 20, 1888, as relates to GEORGE H. TORNEY and GEORGE MCCREERY, *Captains and Assistant Surgeons*, is revoked.—*S. O. 147, A. G. O.*, June 26, 1888.

WOOD, MARSHALL W., *Captain and Assistant Surgeon.*—Ordered to Fort Randall, Dakota Territory, for duty.—*S. O. 147, A. G. O.*, June 26, 1888.

SHANNON, WILLIAM C., *Captain and Assistant Surgeon.*—Ordered to Fort Meade, Dakota Territory, for duty.—*S. O. 147, A. G. O.*, June 26, 1888.

MCCREERY, GEORGE, *Captain and Assistant Surgeon.*—Ordered to Fort Warren, Mass., for duty.—*S. O 147, A. G. O.*, June 26, 1888.

JOHNSON, RICHARD W., *Captain and Assistant Surgeon.*—Designated as Medical Officer for a camp of instruction in rifle practice, to be established at Fisher's Island, N. Y. (near New London, Conn.), on July 2, 1888, and to continue during the months of July, August and September, and is ordered to proceed to Fisher's Island in proper season and report to the commanding officer for duty.—*S. O. 131, Division of the Atlantic* June 28, 1888.

GANDY CHARLES M., *First Lieutenant and Assistant Surgeon*—Granted leave of absence for three months, to take effect on or after July 5, 1888.—*S. O. 145, A. G. O.*, June 23, 1888.

CLENDENIN, PAUL, *First Lieutenant and Assistant Surgeon.*—Leave of absence granted in S. O. 59, Department of Texas, June 4, 1888, extended one month.—*S. O. 149, A. G. O.*, June 28, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JUNE 30, 1888.

Surgeon A. M. MOORE ordered to Naval Station New London.

AUSTIN, A. A., *Passed Assistant Surgeon*—Detached from "Gedney" and wait for orders.

OWENS, THOMAS, *Assistant Surgeon.*—Detached from Naval Station, New London, and ordered to Coast Survey Steamer "Gedney."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JUNE 30, 1888.

VANSANT, JOHN, *Surgeon.*—Granted leave of absence for ten days. June 25, 1888.

MEAD, F. W., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days. June 28, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

THE CEREBRAL PALSIES OF CHILDREN.

Clinical Lectures delivered at the Infirmary for Nervous Diseases.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, PHYSICIAN TO THE PHILADELPHIA AND UNIVERSITY HOSPITALS AND TO THE INFIRMARY FOR NERVOUS DISEASES.

LECTURE I.

INTRODUCTION. INFANTILE HEMIPLEGIA.[1]

INTRODUCTION.—Dividing the motor path into an upper, cortico-spinal, segment, extending from the cells of the cortex to the gray matter of the cord, and a lower, spino-muscular, extending from the ganglia of the anterior horns to the motorial end plates, the palsies which I propose to consider in these lectures have their anatomical seat in the former, and may result from a destructive lesion of the motor centres, or of the pyramidal tract, in hemisphere, internal capsule, crus or pons.

Certain general features define sharply from each other palsies of the upper and lower portion of the motor path. When the latter is affected as in the common infantile spinal palsy, poliomyelitis anterior, we have the combination of paralysis with rapid wasting, early loss of reflexes, absence of rigidity and marked changes in the electrical reactions. On the other hand, in involvement of the upper segment, when the lesion is cortico-spinal, anywhere from the motor cells of the cerebrum to the gray matter of the cord, there is paralysis with spasm or disordered movements, exaggerated reflexes, neither rapid nor extreme wasting and normal electrical reactions.

The clinical picture presented by diseases of the upper segment is very varied, depending partly on the nature, partly on the extent of the lesion; and while on certain grounds it would be preferable to classify and consider the affections on an anatomical, or, perhaps, better still, on an etiological basis, we may, for clearness and convenience, adhere to custom and classify the cases according to the distribution of the paralysis, whether hemiplegic, diplegic or paraplegic. The cases are usually arranged under the generic terms cerebral palsies—the German *Cerebrale Kinderlähmung*—or spastic palsies, while the specific designation indicates the distribution of the paralysis, whether unilateral, bilateral, or paraplegic.

Without entering into historical details, it will be sufficient to note that the publication, in 1884, of Strümpell's paper[1] seems to have aroused special interest in the subject. Since then, the monographs of Gaudard[2] and of Wallenberg,[3] the contributions of Ranke,[4] Bernhardt[5] and Kast,[6] in Germany, of Jules Simon,[7] Richardiere,[8] Jendràssik and Marie,[9] in France, of Ross,[10] Hadden,[11] Wolfenden,[12] Abercrombie[13] and Gowers,[14] in England, have extended and systematized our knowledge of these cases.

The valuable papers by McNutt,[15] Sinkler,[16] Wood,[17] Hatfield,[18] Knapp,[19] Bullard and Bradford,[20] Seibert, Caillé, J. Lewis Smith,[21] and quite recently Lovett,[22] show that the question has not failed to attract the attention of American observers.

It is a pleasure to speak specially of the work of Dr. Sarah J. McNutt, of New York, which Gowers has recently characterized as "by far the most valuable contribution to medical science that the profession has yet received from members of her sex."

The kindness of my colleagues, Dr. Weir Mitchell and Dr. Wharton Sinkler, has enabled me to utilize their cases as well as my own, and makes the material upon which these lectures is based exceptionally large, much larger in fact than has been heretofore analyzed from any clinic. I have to thank, also, Dr. Kerlin, of the Pennsylvania Institution for Feeble-minded Chil-

[1] I am indebted to Dr. C. W. Burr, the resident physician, for much valuable assistance in the preparation of these lectures.

dren at Elwyn, for placing at my disposal the cases under his care; and to Dr. Wilmarth, his assistant, for anatomical data.

The cases may be arranged as follows:

		Cases.
Hemiplegia.	Infirmary	97
	Penna. Instit F. M. C.	23
	Total	120
Bilateral hemiplegia		19
Paraplegia		11

A total of 150 cases of cerebral paralysis.

It is of interest to compare the relative frequency of the cerebral and spinal forms of infantile paralysis. During the period in which there have been at the Infirmary about 120 cases of the former, there have been nearly 500 cases of the latter, so that the proportion is about 1 to 4.16.

I. INFANTILE HEMIPLEGIA.

Synonyms.—Hemiplegia spastica cerebralis (Heine). Hemiplegia spastica infantilis (Bernhardt). Acute Encephalitis der Kinder (Strümpell). Die Atrophische Cerebrallähmung (Henoch). Agénése cérébrale (Cazanvielh). Sclérose cérébrale, atrophie partielle cérébrale (French writers).

Etiology.—Of the 120 cases, 57 were boys and 63 girls. Right hemiplegia occurred in 68, left in 52 cases.

Age at onset not given	9

Thus the greatest proportion of cases occur during the first three years of life.

Of the *congenital* cases, five presented no record of injury during delivery, and the affection was noticed either just after birth, or very early, without definite onset.

Case II.—Joseph C., æt. two years and a half. H., 203.[1] The mother, when pregnant with him, had chorea from the second to fifth month. When born the left arm was cold and white, and the child never used the left side. A squint has developed during the past six months. The left arm and leg are small, stiff and shrunken.

Case XXXV.—Genevieve C., æt. two years and nine months. I. P., 4, 38. Eleventh child, birth normal; no convulsions; dentition normal. After birth, the mother noticed that the child used the left hand rather than the right, and this condition has persisted. The child now walks, but with a hemiplegic gait. Rigidity at the right elbow; contractures; difficult to extend. Intellect defective.

Case XLIII.—Tillie N., æt. twenty-three months. I. P., 3, 185. One of seven children; others healthy. Mother noticed since childbirth a contraction of fingers of right hand, and loss of power in arm; also weakness in right leg, especially at ankle. No history of fever. Born naturally at full term.

Case LXVII.—Henry B., æt. sixteen years. H., 262. Had seven spasms during the first twenty-four hours after birth, followed by loss of power on right side. Began to walk at twenty-two months. Learned to talk easily. Had a talipes equino-varus of right foot, which was operated upon. Began early to have choreic movements of the right side. Goes to school, and is intelligent. The right arm is apparently as well developed as the left, but the muscles are rigid. Very little voluntary motion. At rest, there is frequent spasm of the arm, the fingers are thrown out into irregular movements, and the arm is thrust out at right angles, or jerked behind him. This is very marked on excitement. The right leg is an inch shorter than the left, and not so well developed. When walking the leg is very rigid, and he turns the foot out. The leg is frequently extended when at rest. No rigidity of muscles of neck or face.

Case LXVIII.—Minnie C., æt. eight years. H., 281. Mother noticed that as soon as the child began to crawl and play it seemed paralyzed on the right side. Cannot fix the date of onset; there have not been convulsions. The right arm and leg can be moved, but they are somewhat wasted, and are the seat of irregular choreic movements whenever an attempt is made to use the arm or to walk. There is slight irregular movement on the right side of the face, when talking.

In the first three cases, the condition is stated to have been observed from birth, and, in the last, there was no seizure to indicate the onset, and in it, too, the paralysis was probably congenital. In the fourth case, there were convulsions during the first twenty-four hours similar to those which, as we shall see, usher in the majority of these cases.

Abnormal conditions of the mother during pregnancy, or accidents, are mentioned as possible causes, and, in a few of the cases, we find a record of sudden fright or unusual mental distress; but it is very doubtful how far such influences can be connected with the affection of the child. In such an instance as the following, the fright of the mother early in pregnancy cannot have had the slightest effect in inducing hemiplegia.

Case VIII.—Luther P., æt. four years. H., 279. Is the fourth of five children. Natural labor. Mother states that she was badly frightened at the third month, and to this she attributes the paralysis of the child. Had spasms while teething, but, as early as the third month, it was noticed that he did not use one side well. The right arm and leg are stiff and contracted. Began to walk when two years old. The speech is somewhat affected. Has had only one convulsion since teething.

Except in a few cases, no special mention is made of the existence of nervous disease in the parents, and the following is the only case in which there was a marked history of *alcoholism*.

Case LXVIII.—Florence H., æt. seven years. I. P., 359. Father and mother addicted to drink. Is paralyzed on left side. Can get no history of its origin. Left hand

[1] The letters and numbers after the cases refer to the Hospital Case-books.

shows marked choreic movements. Gait hemiplegic. Has *petit mal*, and, occasionally, severer fits, in which she falls.

I have been rather struck with the vigorous, healthy-looking condition of the mothers with hemiplegic children whom I have seen at the Infirmary.

Syphilis is not often mentioned as a cause of infantile hemiplegia. It was noticed in only two of Gaudard's[1] series, and Wallenberg[2] alludes to it, but does not give any instances. In Abercrombie's[3] series of fifty cases, four of the children had congenital syphilis. The following is the only case on the records in which there seems to be a pretty definite history of this disease.

Case LXIV.—Annie F., æt. two years. I. P. A., 225. Parents healthy. Of nine children, only two are living. Several died immediately after birth. Mother has cicatrices about the mouth and nose, due to a rash which came on during pregnancy. The child was well when born. When eight months old, fell off a chair; was not insensible, but that evening had "spasms." When ten months old, had spasms while cutting teeth. There were fever and a great increase in the general tenderness which had existed all over the body. There was no coma. About a week after the convulsions the mother noticed that there was complete loss of power in the left arm and leg. The child gradually regained use of the leg, and, when a year old, could stand on the leg, but she cannot yet stand alone. There was no facial palsy. *Status præsens:* A pale, but plump child. Is not very intelligent; can say only two or three words. She has thirteen teeth, all beginning to decay. The left arm is not wasted, but is flexed and contracted, and cannot be moved. The fingers are clenched. The left leg is swollen and softer, but there is no difference in the length. Four months ago she began to have spasmodic contractions of the affected arm and leg, lasting for about five minutes, and occurring several times each day. The arm would be jerked up, the leg twitched and the eyes become fixed. No twitching of face. Just before they come on she gets quiet, and, if nursing, drops the nipple. Immediately after, she draws a deep breath, and is then as bright as ever. The child was brought back when eight years old, and note merely says "decidedly idiotic."

The association of paralysis and mental defects with *difficult* or *abnormal labor* has been insisted upon by many writers, and, on several occasions, Dr. Sinkler[4] has called attention to the subject, in connection with cases brought to the hospital.

In two cases the children were born prematurely. In Case LI. the mother had a fall, and delivery occurred at the eighth month. The child, however, throve until the second year, when it had convulsions and became paralyzed on the right side. There was, probably, no connection whatever between the premature delivery and the onset of the disease, but, in the following instance, the affection probably dated from a few weeks after birth.

Case LXVI.—Andrew S., æt. one year. A seven months' child; very thin when born. When three weeks old had many convulsions, very severe. For six months, on and off, there were fits every day. When lifted, and legs stretched, always screamed. When about five or six months old it was noticed that the left arm and leg were not moved. There has been no improvement, and now the fingers are contracted, and the forearm flexed on the arm. Can raise the arm, but does not use it. Left leg as long as right, but the foot seems shorter. Limb flexed at knee, but she can move the leg and toes. Does not sit alone nor stand. Died a week after first visit.

In three of the cases of bilateral hemiplegia the children were born at the seventh month; and in two of the cases of paraplegia the delivery was premature. In twenty-eight of Little's forty-nine cases of spastic rigidity,[1] eight of which were hemiplegias, the birth was premature, in either the eighth or ninth month.

Injury with the forceps.[2] Fissures and fractures of the cranial bones, with hemorrhage or contusion of the brain substance, are well recognized by obstetric writers as among the untoward results of forceps delivery. The parietal bones are most frequently involved. Unless bleeding occurs, or contusion of the subjacent cortex, the effect is not serious. In the special monographs relating to cerebral palsies in children, we do not find many cases of the kind. Thus, in Little's[3] paper, which deals particularly with the relation of abnormal parturition to physical defects in the child, there are only four instances in which the forceps was used, and there is no statement of actual injury. Gaudard,[4] in a review of eighty cases, met with no observation of the kind in the literature, and Wallenberg,[5] in his analysis of 160 cases, notes that in only six instances was difficult labor mentioned as a cause, and he says nothing about the forceps. The Infirmary records contain the following cases, nine in number, in which the children were delivered with forceps.

Case VI.—Ada W., æt. three years. H., 249. No other children. The mother had a convulsion during labor and the child was born with instruments. Very early it was noticed that she did not use the right arm and leg properly, and this continues.

Case XII.—Albert McM., æt. eighteen months. H., 295. Instrumental labor; head slightly injured. Paralysis noticed October, 1884, just after a fall. Whole left side is affected; contractures of arm and wrist. Has no convulsions.

Case XVI.—Mildred M., æt. three months. H., 326. The second child. Was born with instruments. Labor tedious, head locked. Has no marks; well-nourished, healthy child; head symmetrical, a little fuller right than left. Legs never affected, reflexes good. Left arm paralyzed, smaller than right, three-quarters of an inch less in circumference of forearm. Fingers contracted. Improved somewhat under treatment.

[1] Little: Obstetrical Society Transactions, vol. iii., 1862.

[2] With the revelation of the Chamberlen's secret in the second or third decade of the eighteenth century, and the general introduction of the forceps as an aid to delivery, there was, very naturally, discussion upon the effect of such a measure on the child's head; and to this Sterne gives popular expression when, in *Tristram Shandy* (vols. i. and ii. of which appeared in 1759), he makes the breaking of Tristram's nose by Dr. Slop's forceps the beginning of all his troubles. The possibilities of injury to the "delicate and fine-spun web" of the brain are discussed at length by Shandy, Sr., with the Doctor and Uncle Toby.

[3] Loc. cit. [4] Loc. cit. [5] Loc. cit.

Case XLV.—Mary C., æt. one year. I. P., 49. Parents healthy; was born with forceps. Baby did not use the right arm. Now is unable to set up. Right arm is smaller than left, the flexors are contracted, and the fingers are contracted and stiff. Uses the left leg more than the right. There is strabismus; forehead is narrow, no marks; has never had fits.

Case XLVII.—Clarence H., æt. three and one-half years. M., 5, 314. Elder of two children. Other five months old, well. Born with forceps; bears marks of deep lacerations. At two years began to walk, but badly. Walked in a stooping position and on his toes. Momentary spasm six months ago, thought to be brought on by excitement. Fairly well nourished and very intelligent; speaks slowly. Walks with uncertain, tottering gait. Drags left leg, and often falls forward.

Case LXV.—Estella M., æt. three years. I. P. a., 227. Was delivered with forceps after a long labor; head slightly cut. No convulsions, but for the first three months of life had prolonged screaming spells. Mother does not know whether the child was paralyzed at birth, but when she was three weeks old, she noticed that the left arm and leg seemed perfectly powerless. When one year old, she began to use the leg. Has now paralysis of left arm; can lift it, but the hand is practically useless, though she can move the fingers. The left leg is very little smaller than the right. Gait hemiplegic. Intelligent.

Case LVII.—Kate F., æt. four years. M., 6, 18. Born with instruments; bears mark on face; small spot in skin and nodular thickening on right frontal bone. Never has used left hand and arm and left leg properly; cannot grasp well with left hand. Left hand smaller than right; cannot pick up small objects with the fingers; can walk and run, but not well. Left foot stiff; flexion and extension difficult. Apparent rigidity of ankle-joint. Muscles well developed. Walks on outer side of foot, and chiefly in the ball of foot. Knee-jerk increased very little. Left leg is colder. Is bright and intelligent.

Case LXXVI.—Floyd S. L., æt. six years. I. P_3, 33. Supposed to have been injured at birth by forceps. Was very inert during the first three months of life. After this, the mother noticed peculiar spasms, first in left leg then in right arm. Got well except in the right arm, which is choreic and palsied.

Case XCVII.—Lulu H., æt. five years; the fifteenth child. Others born living. Four children have died, two of convulsions. Mother in labor three hours; forceps applied, as there was some difficulty. Child resuscitated with great difficulty. Bears the scars of the forceps in right temporal region, just within line of the hair, and top of the right ear is scarred. On the left occipital region low down a scar. The wounds did not bleed much. On the second day child had a convulsion, lasting many hours; never has had another. When about three months old, it was noticed that the left hand was not used, and the face was crooked; and at the eighteenth month, when she began to walk, the left leg was seen to drag. *Status præsens:* Well-nourished, intelligent looking child. Head well shaped. Slight scars in above-mentioned regions; bones not apparently injured. Left face atrophied, but the muscles move quite well. Left arm not used; is smaller than the right. Hand not contracted; fingers can be flexed. A little stiffness at the elbow. Gait hemiplegic, left leg dragged; it is a trifle shorter and is smaller than the right. The reflexes are not exaggerated. Knee-jerk not obtainable on either side.

In six of these cases the child is said to have been injured by the forceps, and in all the paralysis was either noticed at once or a few months afterward without definite onset. Only one of these cases (XLVII.) appears to have had spasms.

Trauma. In three cases there was a history of injury to the head, one a penetrating wound, and two the result of falls.

Case XVIII.—J. E. K., æt. twenty-seven years. I. P_1, 131. When eleven months old received a wound on the left side of the head from a pitch-fork, which penetrated the skull from one to two inches, causing immediate paralysis of the right side of the body. Had convulsions after it. In fourteen days began to recover. Was five years before he could walk, and he never has regained the use of the right arm, which is rigid and flexed. Leg is slightly contracted at the knee and is stiff in walking.

Case LXII.—Thomas McK., æt. three years. I. P_3, 355. Parents healthy, birth normal. Several children have had chorea. When six or seven months old, child fell down stairs, striking her head constantly. Some time after, the mother noticed that there were irregular movements in the right hand, and the child has never used it properly. The movements are much increased by voluntary efforts.

Case LXXIX.—Wilhelm S., æt. twenty-nine months. I. P. a, 81. When born, healthy. On the tenth day after birth the mother fell down stairs with him, fourteen steps. The head was not cut or bruised. For eight days he seemed very ill and did not take the breast; did not have convulsions. The head became much swollen—"all out of shape." Has never used the left hand since the fall, and the muscles are now in condition of rigid spasm. Left leg not used so well as right. The right parietal region bulges, the left is flattened, which makes the head very shapeless—right, semi-circumference nine and one-half inches; left, eight and seven-eighths inches. There is a large soft rachitic spot on right parietal eminence, very tender on pressure. Fontanelles closed. Has not had any convulsions.

Ligation of common carotid. In Case VII. of the Elwyn series there is the following remarkable history:

Mary P., æt. twenty-four years. In 1869, when six years old, she had an extensive abscess of the neck following scarlet fever. Ulceration of the right carotid occurred, necessitating ligation, which was performed by Drs. Keys and Getchell. Left hemiplegia followed and has persisted. *Status præsens:* Well grown but slightly built woman. Left hemiplegia. Wrist flexed immovably at right angles; thumb held in palm; fingers flexed, but can be moved a little. Arm somewhat wasted. Drags left foot. Left leg a little wasted. Face not affected. Is bright and intelligent. Is not epileptic.

Infectious disease. It is well known that both cerebral and spinal palsies may follow any of the specific fevers. Gaudard mentions whooping-cough and diphtheria among the possible etiological factors. In Wallenberg's statistics of 160 collected cases, 9 are stated to have followed measles; 13 scarlet fever; 3 diphtheria (and croup); 6 epidemic meningitis; 3 whooping-cough; 4 typhus (abdominalis); and 2 vaccinia.

Marié[1] has reported two cases illustrating the connection between infantile cerebral hemiplegia and infectious diseases; one came on with whooping-cough, the other followed mumps. Abercrombie lays special stress on the importance of this factor, which is noted also by Strümpell, Bernhardt, Gowers and others. In our series, in 16 cases the disease came on in connection with, or just after, an attack of one of the infectious diseases.

Scarlet fever: seven cases.

Case III.—John K., æt. twelve years. H., 231. Family history good. Was well until July, 1880, when he had a bad attack of scarlet fever; ill for two months and had dropsy. Became very thin after the dropsy subsided; had retention of urine. Convalescence slow—had otitis media and a suppurating cervical bubo. The mother noticed loss of power on the right side as the dropsy disappeared. This persists, and the leg is now weak. But both are getting stronger.

Case XIII.—Emma G., æt. seventeen years. H., 300. Was healthy as an infant and child. Has not yet menstruated. When fifteen, had scarlet fever, a severe attack followed by dropsy. Was ordered a warm bath and while in it was seized with paralysis of the right side and loss of speech, and was unconscious thirteen hours. Was in the bath three-quarters of an hour. Had fever which lasted three days. Was in bed for a month. Gradually recovered use of leg. Gait is hemiplegic. Arm stiff at elbow and wrist and is held flexed. Reflexes exaggerated on right side; speech is still a little thick; a little paresis of right corrugator supercilii. Apex beat of heart forcible; loud blowing systolic murmur.

Case XVII.—Wm. Mc., æt. four years. $M._5$, 37. The seventh child; six years elapsed between sixth and seventh. Was well until November, 1884, when he had scarlet fever; had dropsy and also very bad throat with it. Shortly after, he had convulsions and became paralyzed on the right side; recovered power gradually, but has never spoken since. Said a few words just after the spasms. Is a strong, well-built child. No note as to spasm of the right side.

Case XXIV.—John W., æt. four years. $I. P._1$, 139. Was healthy when born; other children healthy. When ten months old could walk and was quite well; was attacked with summer complaint, which left him weak for several months. When two years and three months old, had a *scarlet rash*, from which he recovered and was walking about. Two weeks after, he arose one morning all right, seemed well and took his breakfast. Went to sleep in the morning, as usual, and the mother noticed that he began to pant and the mouth was drawn to the right. For a week he had a series of convulsions and lost power completely in right side and could not speak. In four or five months the speech gradually returned. Began to walk last spring. Convulsions have not returned. Intelligence below par; talks and his memory is good. Right arm feeble and contracted, and the fingers are flexed. Gait hemiplegic and the leg is stiff.

Case XXVIII.—Cassie McA., æt. twenty years. I. P. b., 85. Small, thin, pale girl. When between seven and eight years old had a severe and prolonged attack of scarlet fever, during which she was for a time insensible. Does not know if she had fits. Right-sided hemiplegia came on during the attack and has persisted ever since. The face has improved, but the arm and leg have not grown, and there is a marked spastic condition of the muscles. Muscles respond to induced current.

Case LXX.—Alice R., æt. twenty years. H., 195. Was imperfect in some way at birth; the head was bandaged; was supposed to have water on the brain. She got better; no special feebleness noticed at that time. At ninth month, scarlet fever; feebleness on right side followed. Did not learn to walk until three years old; at first seemed to walk all right, but soon noticed that she turned the right ankle out, for which a brace was applied. At age of ten, the right tendo-Achillis was cut. There was a gradual leaning to the right side, with curvature of the spine. The right arm and leg did not seem to grow proportionately to the left. *Status præsens:* Is emotional. Slight loss of power on right side of face and uncertainty of movements, which are jerky. Great incoördination on attempting to pick up objects with right hand; movements choreic and weak. Some loss of feeling in right hand. Right leg; sensation better than in right arm. Temperature lower on right side than on left. Measurements of right arm and leg from one-half to one inch less than left.

Case LXXXIII.—Annie K., æt. five years. $I. P._3$, 187. Third child. Others healthy. Family history good. When two and a half years old, in October, the child had a mild attack of scarlet fever, followed by whooping-cough; one day the mother noticed at table that the child had suddenly lost power in the leg and arm of the right side, and that the face was drawn. This was quite sudden, without any premonition. The paralysis persisted, though improving. *Status præsens:* Opens and shuts the right hand, but does not use it habitually. Movements of the arm and forearm good, but constant choreic motion, and it is thrown about, particularly behind her, as she walks. The right foot strongly inverted; gait hemiplegic; toes flexed. Walks on the toes and wears out the nails. No special atrophy of the right ride.

Measles: four cases.

Case XXXII.—Richard B., æt. twenty-five years. Con. Dis. 2, 215. Was healthy until eighteen months old, when he had measles, followed by otitis, during which fragments of bone came away. He then had convulsions and left hemiplegia, which latter has persisted. The arm is short and stiff—the forearm much shorter than its fellow. Great stiffness; claw-hand. Hemiplegic gait. He has a little difficulty in speech. Intellect is pretty good. The convulsions became worse about the tenth year, and he now has attacks at intervals of a week or two.

Case LXXXII.—John C., æt. two and a half years. $I. P._3$, 55. Is the fourth of five children. Cut teeth early. Was well and healthy until last autumn, when he had a spasm lasting four hours. Convulsion general. Next day seemed bright and well. Six weeks ago the other children had measles, and this one, on the second day of the eruption, had a convulsion lasting six hours, after which there was right hemiplegia, with loss of speech, which continued two days. Then convulsions began again, with less severity; sometimes more marked on one side than on the other. He had, in all, about eighty fits. In about two weeks there was improvement in the paralysis, which has continued, and he has, for the past two weeks, been walking. No fits since the eruption disappeared. A discharge from the ear began six weeks

[1] Progrès Médicale, 1885, No. 36.

ago; is now stopped. Appears to understand what is said, but not fully. Head large and square, slight depression at anterior fontanelle, which is closed. Is irritable. There are distinct choreic movements of right arm, which he rarely uses, and only when the left is held. There is evidently loss of power. Leg seems to have recovered perfectly.

Case XXXVII.—Bessie K., æt. three years and two months. I. P_4, 73. Well until the eighteenth month; could walk. During the early stage of measles was seized suddenly with spasms and was unconscious for eleven hours. Had vomiting; paralysis of right side noticed immediately after and loss of speech. Has recovered use of leg and can run. Arm affected. Cannot talk. Intelligence not good.

Case I. (Elwyn series).—Jennie S., æt. fourteen years. In institution five years. Was well and strong as a baby until the twelfth month, when she had measles, followed by paralysis of the right side. Is intelligent. Arm stiff; not much wasted. The fingers move irregularly at times. Under the influence of emotion the hand gets very stiff, but when she is quiet it relaxes and she can pick up objects. Leg well nourished; very rigid; drags it much in walking. Knee-jerk not obtainable. No epilepsy.

Whooping-cough: three cases.

Case LXXXVIII.—Given under scarlet fever, which preceded the whooping-cough.

Case LXXXIX.—Kate B., æt. seven years. I. P_3, 248. Has been a healthy child. Last winter had whooping-cough, which lasted into the spring. In May, 1883, had a convulsion, suddenly, which lasted three hours and was followed by paralysis of the right side and aphasia. Did not attempt to walk for two months. Right arm improved, and face did not seem much affected. Gait is hemiplegic. Articulation is now perfect. Can flex and extend the arm and forearm, but has no power over the fingers. Thumb strongly adducted; wrist flexed. There is at times large tremor of the whole arm, especially when at rest. The right leg is stiff, but she drags it. The toes are turned in, but she gets along very well. Intelligence unimpaired.

Case VI. (Elwyn series.)—John D., æt. fourteen years. Difficult, instrumental labor. Well until two years old, when he had whooping-cough, followed by brain fever and left hemiplegia. Arm stiff and wasted; hand flexed; irregular movements in fingers. Leg wasted. Gait hemiplegic. Choreic movements in left facial muscles. Is a low grade imbecile and has epilepsy.

In the following case *cerebro-spinal meningitis* was stated to be the cause of the trouble, but it was most probably a mistaken diagnosis, as the symptoms are just those which occur in the majority of the cases.

Case XXI.—Lily H., æt. four years. I. P_1, 85. Other children healthy. Was normal as a baby. When nineteen months old had an attack which was called cerebro-spinal meningitis; a series of convulsions for eleven days, on recovery from which the left side was paralyzed. When seen again, at the age of six years, there were marked arrest of development of the left arm and spasm and contractions of the paralyzed side.

In one instance the attack came on after *dysentery*.

Case XXII.—Gussie H., æt. six years. I. P_1, 125. Was never a very healthy child. When fourteen months old had a dysentery, after which she had two severe convulsions and coma for several hours, and seemed unconscious for six days. The left side was convulsed for three days. When she roused, it was noticed that the left side was paralyzed—face and extremities. In about three weeks it began to improve. In three months began to walk, and within a year could walk alone. No convulsions since on left side, but one general convulsion. Talks with difficulty. Left-sided spasmodic paralysis. Gait hemiplegic.

Vaccinia: There are two instances in the literature in which the hemiplegia came on during vaccination. One is given by Heine in his work on *Infantile Palsy*.[1]

Case XXVIII. (given in Wuillamier's thesis).[2]—J. L., æt. five months. Well until ninth month; vaccinated, and toward the close of the process there was fever, with a general papular eruption. Convulsions came on, followed by loss of power in the left side. Subsequently, epileptic attacks and feeble-mindedness.

The following case I saw with Dr. Morris J. Lewis.

Case XCIV.—A. L., æt. seven years; a seven months' child, vaccinated by Dr. Gerhard when she was about four months old. During the height of the vaccination there were convulsions, chiefly on left side, which occurred very frequently and were followed by deep coma. It was some time before the paralysis was noticed—some months. Now she has left hemiplegia. Arm wasted; contractions. Gait hemiplegic. Intelligence defective; speaks badly, but she is learning rapidly under systematic instruction.

In five or six cases the children had had convulsions repeatedly before the onset of the hemiplegia, and it is possible that the *convulsions* caused the lesion on which the paralysis depended.

Case XXVI.—Bruce B., æt. nine years. I. P_1, 207. Has had fits since the age of two years, at least once a month. They were general, and he fell in them. Eighteen months ago, after an unusually severe attack, with seven hours of unconsciousness, he awoke paralyzed on the right side; speech not affected; no loss of sensation. In three weeks he began to use leg. Has not had convulsions for a year. There is still difficulty in using the arm, which is stiff, and the movements incoördinate.

Case XXXIX.—C. M., æt. three years and three months. I. P_3, 237. Mumps two years ago; has had spasms ever since. One week before Christmas had a hard spasm, which was followed by right hemiplegia. Unconscious for six hours after attack. Could not walk for two or three days. Has not had spasms since. Leg and arm have improved. Rigidity of arm increased by passive motion. Can extend and flex arm; can extend but not flex fingers. Walks lame on account of contraction of extensors.

Case LXVIII.—John F., æt. seven years. I. P. b., 183. Mother died suddenly; six brothers and sisters, all healthy. Commenced having fits at three years. Has convulsions every six or seven weeks. When six, had a very severe fit, lasting two or three hours. Worked all the time. Fit lasted until 12 P.M. Awakened with a "screech." Lost hearing and speech. For ten days he moved his whole body. Had convulsive movements and contractions. When he began to improve, noticed he could not move right hand. Health excellent. Mind much impaired. Does not move right arm. Nutrition

[1] Spinale Kinderlähmung, 1860. Zweite Auflage.

[2] De l'epilepsie dans l'Hemiplegie spasmodique infantile. Paris, 1882.

about equal. Right hand colder. Grinds his teeth constantly, night and day. Right arm below elbow smaller than left. Muscles of right arm contracted, will yield, but immediately return. Plays, amuses himself. Takes no notice of others. Right leg a very little shorter than left. Right foot much colder than left, but muscles firm. Tendency to varus in right foot.

Case LX.—S. S., æt. twelve years. C. D. C., 57. Family history good. Healthy and strong until sixth year; intelligence very good. Six years ago mother noticed a twitching of left side of face, lasting not more than one minute, and only once a day. Had had no fall, no sickness of any kind. Soon the attacks of twitching of face became more frequent, two or three daily. Head always drooped to left side, and he seemed unconscious, but immediately afterward returned to play. More frequently attacks of twitching of face at night. Two years after first attack of twitching of face, had a general convulsion of left side; was lying asleep at the time, and attack lasted only a few minutes; did not wake up. Next morning early, while asleep, had another attack, which lasted one hour; got up immediately afterward, and seemed as well as ever. This attack was confined to left side; was paralyzed completely for one month after this; loss of speech. Paralysis suddenly left, and power to speak returned. The convulsive attacks have continued at the rate of from one to twenty per diem, and always during sleep, never when awake, generally at night, but, if asleep during the day, may have an attack. Face flushed during attack, afterward pale. Never bites tongue nor foams at mouth. These attacks continued to increase until two years ago. At this time began to lose power in arm; weakness extended to legs and, finally, could not move head, and lost power of speech. No palsy of bladder or rectum. No loss of sensation or hearing. In one year power began to return in hand, and gradually returned to legs and head. Still speaks very indistinctly. *Present state:* No paralysis of arms or legs. Speaks very indistinctly; mother only can understand him. Mind greatly weakened; and is irritable. Fits occur every night; generally has one to three nightly, and if bromide is neglected, will have a greater number. Always voids urine during a fit. Fits last two minutes, and confined to left side.

Case XCII.—Della W., æt. two years. C. D.$_2$, 950. Convulsions began two hours after birth, and have continued ever since. These are of long duration, and affect the right side more than the left. Six months ago, after a severe fit, she lost power on the right side, and it persists, but is now partial. There are constant choreic movements in the right hand.

These cases are of interest, as confirming Goodhart's[1] view that the convulsions may cause the hemorrhage, which leaves permanent damage to the brain.

In the following case the hemiplegia came on after violent *vomiting*, caused by eating pokeroot.

Case LXIII.—Wm. R., æt. thirteen. I. P.$_3$, 31. Was well until fifth year; at that time ate some pokeroot, which made him violently sick at stomach; the attack lasted all day. After vomiting, fell into a profound stupor—was thought to be dead. When he awoke had complete left hemiplegia, entire loss of power, face as well as limbs. Could not move for three or four months. Recovered slowly, leg first, then arm. *Status præsens:* Muscles well developed. Has every motion of left arm and forearm. Can flex hand, but not well, every effort to flex produces more or less extension. Has also lock-spasm of hand; fingers press tightly in palm; extends them by producing extreme flexion of wrist by other hand, which produces reversed condition, and enables him, with aid of other hand, to unlock the fingers. There is choreic movement of hand resembling athetosis. Sometimes hand will not close. All muscles of left arm and shoulder are in constant motion. Muscles well, indeed, overdeveloped. When asleep, spasm subsides completely. Drags leg, but there are no spasmodic movements.

We should naturally think that *embolic processes* had much to do with the production of hemiplegia in children, but neither in the literature nor in our records is there support for this view. In the great majority of the cases the lesion supervenes before the onset of those affections with which endocarditis is associated. Of Wallenberg's cases, only five had endocarditis and embolism. A case reported by Taylor,[1] illustrates this condition very well: A child aged, five years, with scarlet fever, had convulsions on the fourteenth day, after which a right-sided paralysis remained. There was also partial gangrene of the hand, and dropsy of extremities. The autopsy showed embolic softening in left hemisphere, infarct in kidney and recent mitral endocarditis. Here the connection is very evident, and it is surprising not to find a larger number of cases of this kind. The only instance of embolism on our records is of a similar nature, and is given among the scarlet fever cases. The girl, æt. fifteen years at the time, had dropsy after the fever, and was ordered a hot bath, in which she was suddenly seized with right hemiplegia and aphasia. That this was embolic is likely from the sudden onset, and from the presence, eighteen months afterward, of a well-marked apex systolic murmur, the result, no doubt, of an endocarditis at the time of the scarlet fever.

In speaking of the morbid anatomy, we shall refer to the fifteen cases, of the ninety autopsies collected in the literature, in which there was vascular obstruction; seven of them were embolic.

ORIGINAL ARTICLES.

AURAL VERTIGO.[2]

BY CHARLES H. BURNETT, M.D.,
OF PHILADELPHIA.

AURAL vertigo differs from other forms of vertigo in owing many or all of its phenomena to disease of the ear. This latter lesion may be either entirely causative, or it may be only promotive of the vertigo. This disease has many forms, since the aural irritation may lie in the external, the middle or the internal ear. The entire train of phenomena, regardless of the seat of primal irritation, has been called Ménière's disease. But as both Flourens and Deleau, many years before Ménière, described this peculiar aural disease, the affection might be termed, with

[1] British Med. Journal, 1880, ii.

[2] Read before the Medical Society of the State of Pennsylvania, June 7, 1888.

or Deleau's disease. A fairer and more scientific nomenclature, however, is Aural Vertigo. The apparently same ear-disease does not always produce identical symptoms of vertigo. Sometimes no symptoms of vertigo are produced by the same form of aural disease which in other subjects evokes vertiginous symptoms. The neuropathic diathesis is well marked in most cases of aural vertigo, and hence we conclude that a neuropathic subject, with an aural lesion, is most likely to become vertiginous, and to suffer from aural vertigo. In any case, the neurotic, or neurasthenic, subject is more likely to become vertiginous from any cause, and very easily from irritation in the auditory apparatus.

Aural irritation is competent to produce vertiginous symptoms because of the peculiar nature of the semicircular canals in the labyrinth. These canals owe their peculiar relation to equilibration to the fact that the auditory nerve contains motor fibres, which chiefly pass to the peduncles of the cerebellum, and to the spinal cord. But some of these motor fibres of the auditory nerve pass to the ampullæ in the semicircular canals, thus instituting an auditomotor connection between the internal ear, the cerebellum and the spinal cord. Without attempting to locate in the semicircular canals a vertiginous centre (as some would), it is an admitted fact that irritation of these organs and of the inferior peduncles of the cerebellum produce identical phenomena of vertigo, reeling, nausea, vomiting, etc. This irritation may arise in different ways, and be communicated by various routes to the brain.

In the earliest cases of aural vertigo ever described, the irritation was not only supposed to spend itself upon the internal ear—*i. e.*, on the semicircular canals—but was supposed to be of an apoplectiform kind, and to arise in the internal ear.

It is a fact that post-mortem examination in some cases of ear vertigo reported by Ménière, and also by Moos and others, revealed in the labyrinth and semicircular canals serous and sanguineous effusion, with more or less destruction of the soft tissues of the internal ear, thus establishing an apoplectiform form of aural vertigo.

Similar phenomena of aural vertigo have been observed, and their pathological genesis established by post-mortem examination in tumor of the auditory nerve (Morris Longstreth and C. H. Burnett). Many cases of aural vertigo, however, are *mechanical* in their origin, and are extralabyrinthine.

Thus, in inflammation in the middle ear accompanied by swelling and extravasation of serum, blood, mucus or pus, great pressure is exercised upon the stapes, in the oval window, and upon the membrane of the round window, both of which communicate with the labyrinth fluid. By this means it is easily seen how increased pressure may be exercised upon the labyrinth fluid and the nerves in the semicircular canals, by pressure upon the two windows named.

Another way in which pressure is exerted is by retraction of the chain of ossicles, carrying inward the foot-plate of the stapes, and pressing upon the labyrinth water. When the air of the drum cavity is absorbed, as it is very quickly if the Eustachian tube is closed by inflammatory swelling, or if the drum cavity is invaded by extravasation, the membrana equal justice (perhaps with more), either Flourens's tympani is pushed inward by the external atmosphere.

Mechanism of aural vertigo explained on a physical model of the middle ear. Thus the chain of ossicles is carried inward and the labyrinth water compromised, especially if the normal compensatory yielding of the membrane of the round window is diminished or stopped by swelling of the mucous membrane over its tympanic surface. Such is the mechanism of aural vertigo in both acute and chronic inflammation in the drum cavity.

The latter conditions are fully explained by some recent post-mortem examinations of Gellé, of Paris.

These examinations of the middle and internal ears, in some cases of undoubted aural vertigo, have shown that either the foot-plate of the stapes had been ankylosed in the *oval* window, or that dense fibrous or osseous closure (ankylosis) had taken place in the round window and its membrane. If either of these conditions occurs, the compensatory yielding of (let us say) the membrane of the round window to pressure exerted by the foot-plate of the stapes upon the lymph and the labyrinth is stopped. The result is, that a very little pressure upon the foot-plate of the stapes exerts unusual force upon the terminal nerve filaments in the semicircular canals, and vertigo ensues. Similar forces act and resultant phenomena occur, if the stapes is ankylosed in the oval window, and sound waves or other forces act upon the membrane in the *round* window (membrana tympani secundaria).

The mechanism of aural vertigo is similar in cases in which the irritation—*i. e.*, pressure inward of the membrana tympani, has its origin in the external ear. This is seen in the vertigo produced by a foreign body, or by any force which presses the drum membrane inward. This, in turn, carries the malleus and the entire chain of bones inward. The stapes is forced unduly inward, and the fluid—the so-called peri- and endo-lymph, in the labyrinth is compressed, the nerves in the semicircular canals receive an undue shock, and vertigo is the result.

In the more acute forms of aural vertigo, the patient is conscious of some irritation in his ear, but neither he nor his physician is very likely to connect the vertigo with aural disease. In the more chronic forms of aural vertigo, some cause, other than the aural lesion, is usually blamed for the vertigo and other cognate symptoms.

If the vertigo and nausea are the chief symptoms, the patient is supposed to be bilious. If to these symptoms, reeling and falling, with or without syncope, are added, the victim is said to be epileptic or apoplectic. In some cases, in which the irritation is from a foreign body in the external ear, the patient may have symptoms of paresis in the arm or leg on the same side.

In many instances of ear-vertigo from tympanic disease, the symptoms are only a slight dizziness and nausea, coming on suddenly after eating, or with a cold in the head. These are most likely to be considered gastric in their origin, or "bilious." Yet vomiting does not always relieve, nor yet treatment for the supposed "biliousness." In the worst forms of aural vertigo, originating in chronic disease of the middle ear, the symptoms are most distressing. The nausea and dizziness may come on suddenly, being generally preceded by tinnitus aurium These symptoms often continue for hours or even days, the patient becomes extremely pallid, the forehead, and in fact the entire body, may be bathed in cold perspiration, the hands even get cold and clammy, and the patient presents the appearance of one in collapse. The mind, however, remains entirely clear, and there is nothing resembling either tonic or clonic spasms. The absence of these, together with the pallor and unobstructed intellect, serve to distinguish such attacks from apoplexy, or epilepsy.

Of course, when the dizziness and nausea are intense, the patient cannot walk, and syncope may supervene from the intense nausea. Nevertheless the pallor will aid in distinguishing aural vertigo from apoplexy. But syncope in aural vertigo is one of the rarest symptoms.

In the so-called apoplectiform cases, in which sanguineous or serous effusion into the labyrinth is supposed to occur, the profound and sudden deafness, the great tinnitus aurium and the vertigo, consciousness being maintained, serve to diagnosticate aural vertigo from apoplexy.

In these cases, the vertigo generally appears in paroxysms, apparently dependent upon variations in health or upon fatigue. In these forms, it will be often found that the subject has been overworked, either as a business or professional man. The deafness is usually permanent and the tinnitus aurium long continued.

In aural vertigo dependent upon a central lesion, like tumor of the auditory nerve, the vertigo and altered gait are constant, and the deafness increasing and profound.

Treatment.—In external-ear-vertigo, when the irritation arises from a foreign substance in the ear, the treatment consists in the removal of the foreign substance. This is most safely and conveniently done by syringing the ear. If the foreign substance has wounded the skin of the auditory canal or the membrana tympani, such lesions must be treated. If the foreign body is an animate one, like an insect, smothering the creature with oil, as soon as possible after its entrance into the ear, will allay the vertigo. The dead insect can then be removed at leisure.

If the irritation productive of aural vertigo is in the middle ear, the treatment must be directed to the cure of the acute or chronic inflammation of the drum cavity, and its causes.

In acute otitis media, the removal of the products of inflammation may be accomplished either by inflation of the tympanum through the Eustachian tube, or by paracentesis of the membrana and letting out the mucus or pus. At the same time, the nares, from which the inflammation has probably started, must also receive attention. In the chronic form of otitis media catarrhalis, the treatment of the nares must be a prolonged one, in order to relieve the narrowing or swelling of the Eustachian tube, which, having cut off the usual air-supply to the drum, has led to a vacuum in the drum-cavity, to retraction of the membrana and the ossicles, inward pressure of the stapes and pressure on the labyrinth water, thus evoking aural vertigo.

In chronic cases like that just described, the equilibrium of the air-pressure on both sides of the membrana and the restoration of the vibratility of the chain of ossicles, with consequent relief to labyrinth pressure, may be brought about by perforation of the membrana tympani. This may be done with a small paracentesis knife; but the relief is of short duration, because the knife-wound heals very soon. A more lasting opening may be made with sulphuric acid.

Previous to this latter operation, partial local anæsthesia may be obtained by instilling a ten per cent. to twenty per cent. solution of cocaine into the ear and allowing it to rest a few minutes in the fundus of the canal and on the membrana tympani. Then, under good illumination of the fundus and the membrana, either by the light reflected from a forehead-mirror or from the electric lamp arranged for the forehead, press a cotton-holder armed with a small dossil of cotton, one to two millimetres (a half to a line) in diameter, moistened with sulphuric acid, against the lower posterior quadrant of the membrana tympani.

This operation causes sharp pain for a few moments, but this is always checked by the instillation of more cocaine. The hearing is usually improved, and the attacks of vertigo much less frequent and severe after the perforation in the membrana is established. Perforations thus made endure for months, and in the meantime the vertigo is relieved or cured.

A more permanent opening in the membrana—*i. e.*, into the drum-cavity—is maintained by excision of the membrana and the two larger ossicles, the

malleus and the incus. This operation relieves the retraction of the chain of bonelets and permits the stapes to have more freedom of motion in the oval window. This can be performed only when the patient is under the effect of an anæsthetic. Then, in order to bring a light with safety near the patient, for illuminating the ear, the electric light as arranged by Dr. S. Sexton, of New York, must be used (portable storage battery and lamp for forehead shown).

The first step in this operation is to excise the posterior upper quadrant of the membrana tympani with a small knife. This is done in order to reveal the incudo-stapedial joint and to permit a separation of the incus from the stapes. The latter must be left intact; the former may be removed or simply allowed to remain turned upward into the attic. The next step should be tenotomy of the tensor tympani, best accomplished by a special form of knife. This done, the membrana tympani is cut around the periphery and the suspensory ligaments of the malleus severed, and the latter bone removed by gentle traction with forceps. The hemorrhage is very slight, and there is usually no inflammatory reaction after this operation. As the hearing is often improved by this operation, and the tinnitus aurium lessened or entirely cured, it has seemed to me fair to assume that aural vertigo in chronic aural catarrh, with profound deafness, which has failed to yield to treatment applied to the naso-pharynx, might be relieved by the operation I have just described. Hence I have performed it for the relief of aural vertigo, with entire success, in a case of this nature. From all of which we may conclude that aural vertigo is very often due to mechanical interference in the sound conductors of the middle ear, relievable by an operation which overcomes this disturbed mechanism in the middle ear and relieves the labyrinth and the semicircular canals from the undue inward pressure of the chain of ossicles, especially the stapes, upon the labyrinth fluid.

A NEW FORM OF ABDOMINAL ELECTRODE.

By ELY VAN DE WARKER, M.D.,
of Syracuse, New York.

The present of a book-weight composed of two narrow rows of quilted cloth filled with shot, making a long, flexible weight that would reach across the open pages of a book, furnished the idea of the shot abdominal electrode as I have made and used it.

It may be briefly described as follows: A circular disk of zinc, to which is connected the binding-post, has attached to its periphery, by solder, half a dozen fine copper wires eight inches long, or of sufficient length to reach across the electrode, which are loosely tacked, as the needle-women call it, to a piece of thick, firm chamois skin, cut the shape and size of the intended electrode. Upon this is laid another piece of chamois of the same size, and the two are then quilted together in rows parallel to each other, and about two-thirds of an inch apart. The spaces made by the rows of quilting are then filled with fine shot; I used No. 7. A thin vulcanized plate, the same size as the zinc disk, is interposed between the chamois and the zinc, on what we will call the contact side of the electrode, so that the current will be diffused through the latter and not directly from the zinc, as electricity always takes the shortest route. For the same reason, the copper wires should be tacked to the upper and not the contact side of the electrode, as there is just enough difference in conductivity between the copper of the wire and the lead of the shot to diffuse the current, the copper having a specific resistance of 112, and the lead of 1213 (Deschanel). This difference in specific resistance is the theory upon which I relied to distribute the current evenly through the electrode, and the result in practice showed that it was correct; but it is evident that if the copper wires had nothing but the wet chamois interposed between them and the skin of the patient, the latter would receive the electricity in streaks corresponding to the distribution of the wires, which would be very clearly mapped out in vivid colors when the *seance* was over.

The electrode is prepared by immersing in water until it is saturated, and thus the chamois, which is a non-conductor in the dry state, becomes as perfect a conductor as water can make it. While we have a pad of very low power of internal resistance, yet the resistance is not represented by the elements of which it is composed, but by the water with which it is saturated. This is true of all large electrodes that are designed to be neutral in the employment of a current of any considerable voltage. The merit of the shot electrode lies in matters entirely outside of purely electrical considerations, and is mechanical, or, it is better to say, operative.

The comfort of the patient, the steadiness of the current, the safety of the surface and the after-results depend not upon the material of which the electrode is composed, because water is the agent that acts as the conducting element between the material of the electrode and the surface in all non-effective large electrodes of this class, but upon the firmness and uniformity of the contact between the electrode and the exposed surface of the patient. I have used several of them, and find that in this respect there is a serious defect in all. One of the best is the clay electrode of Apostoli, which is made up of non-conducting material and depends upon water as the conducting agent entirely; but unless the clay is made very wet it requires great battery strength to overcome the internal resistance offered by the material, and through the respiratory movements of the abdomen, the movements of the patient,

or reflex jerk, the intimacy of contact and the uniformity of pressure are being continually changed; in other words, a make and break in the continuity of the current is continually going on in small areas throughout the surface of the electrode, which accounts for the blotched appearance of the surface when the clay is removed after a *seance*. This can only be prevented by making the clay thoroughly wet. In addition to this the electrode of Apostoli is troublesome and filthy. Large zinc plates covered with absorbent cotton and saturated in a solution of sodium chloride, or covered with soft towelling wet in the same solution, are still more difficult to keep in uniform contact with the exposed surface of the patient. The milliampèremeter instantly shows the variations in contact. If the electrode is held in position by the assistant and the pressure of her hand is relaxed, the instrument will at once register a smaller number of milliampères, but without any indication that the current is broken. When the pressure is restored, the former amount of current is again indicated. The water electrode that some one has invented is simply a great fluid rheostat that modifies the current and requires considerable battery effectiveness to overcome.

The shot electrode that I have made weighs nearly four pounds, and by its flexibility and weight preserves a constant degree of contact and pressure. It adjusts itself to the respiratory movements of the abdomen, coughing or involuntary muscular contractions, without in any way interfering with the uniformity of contact or pressure. The new electrode has given me considerable satisfaction, and I contribute this in the hope that others may be induced to give it a trial. My instrument was home-made, and is more useful than ornamental. Messrs. Waite & Bartlett, of 143 East 23d Street, New York City, are prepared to make the electrode in more durable and workmanlike form.

THE RATIONAL TREATMENT OF STRICTURES OF THE MALE URETHRA.[1]

BY JOHN HARVEY GIRDNER, A.B., M.D.,
INSTRUCTOR IN SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

ANATOMISTS and surgeons, when writing of the male urethra, divide it into portions, called prostatic, membranous, bulbous and penile. While these divisions are quite proper in a certain sense and greatly facilitate description, they are, nevertheless, often misleading, and one is very likely to associate in his mind an essential difference in the construction of the variously named portions of this tube, and these false notions interfere with all subsequent attempts at a clear conception of the causation and proper treatment of strictures of its calibre.

The truth is, the urethral canal is of identical construction throughout its entire length, and the terms prostatic, membranous and bulbous portions have no relation to the tube *per se*, but describe the tissues by which it is surrounded at various points in its course. Picture to your mind an India-rubber tube of uniform construction and nearly equal calibre, leading across country, through which water is to be occasionally pumped; at one point it curves upward to pass over high ground, where it is firmly imbedded and closely surrounded by the earth; at another it dips downward to span a hollow, where there is almost no support around it; again, a boulder supports its under surface, and so on, and you have an excellent sketch of the male urethra. A microscopical section from any portion of the urethra shows the walls to be constructed of elastic and non-elastic fibres running in different directions, and all thoroughly interlacing with each other, and the mucous membrane which lines the canal is paved with many layers of epithelium; in short, nature seems to have exhausted herself in providing that this canal shall be effectually protected against leakage of the urine into the surrounding tissues while passing from the bladder.

We know that it is nature's rule, in so far as she is able, to repair every injury to the organism, whether made by disease, accident or the surgeon's knife. But, unaided, she frequently fails to attain the end for which she strives, while, at other times, in the very act of repairing a breach, she brings about another and more serious pathological condition than the one which she sought to relieve. With the superior intelligence of man over nature, it is our business as surgeons to study nature's methods, and, by aiding and directing them, to bring about the restoration of the part, which, left to herself, she could not have accomplished. Nature's laws and methods never change; the means she would have employed to repair the injuries inflicted by Cain upon Abel are the same which she adopts in a similar case to-day. It follows, then, that every *real* improvement in our art must be based upon the discovery of a new law in nature's code, or upon a more perfect understanding of one already known. Take as an illustration, antiseptic surgery. What is it? Only a strict obedience to one of nature's laws which we have thoroughly learned, viz., that certain secretions, notably the urine, and the products of inflammation shall not remain in contact with unprotected living tissue.

Innovations or new methods of treatment, based upon any other principle than this, are mere experiments, or, what is infinitely worse, are the dictates of fashion, which is unfortunately too common in the practice of surgery.

[1] Read before the Clinical Society of the New York Post-Graduate Medical School and Hospital, April 7, 1888.

Strictures of the urethra are never directly caused by disease or injury, but are the result of the protective and reparative methods which nature adopts to preserve the integrity of the walls of the canal when they are attacked by ulceration or injury from within the tube.

The ulcerative action of the virus of gonorrhœa upon the inside urethral wall is the most common cause which excites this protective inflammation on its outside: but it ought not to be forgotten that every traumatism to the mucous lining of the urethra, whether made by accident or by the surgeon's instruments, if at all serious, will certainly be followed by plastic inflammation and a deposit of organizable lymph opposite the point of injury on the outside of the tube, and between it and the surrounding tissue; this lymph soon becomes organized into connective tissue, strengthens the wall at the desired point and secures its integrity until the inflammation, ulceration or effects of the traumatism within the tube have passed away.

In obedience to another law of nature governing connective tissue, it slowly contracts, and, as it does so, it presses the urethral walls together, and consequently impinges upon the calibre of the tube, and thus a stricture is formed.

The tightness of a stricture depends upon the *amount* of connective tissue thrown out at that point. In the penile portion, where we would expect the virus of gonorrhœa to be the most active, we rarely have tight strictures; the reason is, that in this portion the corpus spongiosum envelops the urethral tube so snugly that only a small amount of connective tissue can be placed between it and the surrounding structures at any one point. The bulbous and membranous portions are the points where the tightest strictures occur; the reason is that around these portions the tissues are very lax; here the urethral tube spans a hollow, as it were, and receives almost no support from the adjacent tissues, and thus abundant space is left around it for the deposit of a large quantity of plastic lymph.

The bulbous and membranous portions are not only the seat of the tightest strictures, but these portions are most *frequently* attacked by them.

The reason for this greater frequency is, because the urethra being most dependent in these portions, the gonorrhœal poison naturally gravitates to, and remains in them; injections into the canal for the cure of gonorrhœa also doubtless assist in driving the virus to these portions.

Stricture, perhaps, never occurs in the prostatic portion of the urethra. The reason is, that the tube curves sharply upward from the membranous through the prostatic portion into the bladder, and there is nothing to force the virus up this acclivity once it is lodged in the membranous portion, and if it should reach the prostatic portion and set up an ulcerative inflammation, the stricture resulting would be only a slight one, for the firm tissue of the prostate gland surrounds the tube so tightly, that only a very slight amount of cicatricial tissue could be deposited between them.

We come now to the treatment of strictures of the urethra. And still keeping Nature's laws in view, let us endeavor to find out what, from her standpoint, are the rational means by which we can both relieve these constrictions and remove or render impotent the cicatricial tissue which has caused them.

From what we have already noted of the peculiarities of strictures in the different portions of the urethra, the subject of their treatment seems naturally to divide itself into two heads, viz., stricture in the penile portion and stricture in the membranous and bulbous portions.

We will first consider the treatment of strictures in the penile portion. We have seen that strictures occur with less frequency in the penile portion, and that they are also rarely so tight as when situated in the deeper portions; we have also seen the reasons for these differences. The methods of treatment generally adopted for relieving these strictures are two; gradual dilatation and pressure by the introduction of steel sounds of increasing size, and by internal urethrotomy.

From the standpoint of antisepsis, the operation of internal urethrotomy is a most glaring inconsistency, and a violation of the known laws of nature, as applied to this part of the organism.

You cannot cut a stricture internally, without at the same time cutting some of the sound tissue in its neighborhood; and, indeed, the advocates of the operation advise that the cut shall extend into the sound urethra behind and in front of the constriction. The amount of it is, in this operation, an incised wound is made through the urethral wall and into tissue eminently adapted for the absorption of any deleterious matter which may come into contact with the wound. It is a wound to which air may find access, one through which instruments are to be passed, which, in spite of our best care, may deposit in it septic matter. It is a wound certain to be constantly bathed with urine, a wound which you cannot see, explore, drain, cleanse or disinfect.

Should the patient escape these dangers of infection, the worst is to follow, for after this traumatism, nature adopts her old method of preserving the integrity of the urethra, and deposits more lymph at the seat of the stricture and in the adjoining healthy tissue, which in time organizes and contracts; and not the old stricture, but a tighter one is formed, and the last state of that urethra is worse than the first.

My own clinical experience of more than ten

years, and the still greater experience of others, which I could detail, had I the time, amply prove the truth of what I have said. Everything said of internal urethrotomy applies equally to divulsion, rapid dilatation or any plan which contemplates a traumatism to the urethral wall.

The so-called gradual dilatation treatment is a misnomer as applied to strictures of the penile portion. It conveys only the idea of stretching, while the most important element in it is the pressure it exerts on the connective tissue surrounding the tube. One of the simplest and best known laws of nature is that pressure on a part causes its absorption. We, therefore, take advantage of this law, and of the fact that the tissues around the penile portion of the tube are comparatively firm, and offer a certain amount of counter-pressure. It is my rule, also, to aid this counter-pressure by allowing each instrument to remain in the urethra for five minutes or more, and during this time to make gentle but firm pressure over the seat of the stricture by squeezing the penis at this point between the thumb and finger, carrying the manipulation all around the organ. In cases in which the deposit of cicatricial tissue was so large that it could be felt as a small hard tumor around the point of stricture, I have been able to note its gradual disappearance from day to day under this treatment. After much experience with this method, I have yet to see a stricture of the penile portion which failed to yield to it, and when dissipated in this way the stricture has not returned in two, three and five years after all treatment was discontinued, as is proven by some of my own cases. This I hold to be the only rational and successful treatment of strictures in the penile portion.

Next comes the treatment of stricture of the deep urethra. The dangers and unnaturalness of internal urethrotomy and allied operations, as we have shown them to exist when the operation is performed in the penile urethra, are doubled if performed in the deeper portions; and with this remark, I dispose of the subject of internal cutting in the deep urethra.

Gradual dilatation and pressure, which we have seen to be so successful in the penile portion, will cure only a limited number of strictures when they are situated in the bulbous and membranous portions. The reasons for the failure are, because, as we have seen, strictures in these portions are, as a rule, very tight, the open space around the tube here allowing of a large deposit of connective tissue; and, furthermore, this same laxity of the surrounding tissues prevents us from getting the counter-pressure, when solid sounds are passed, which the more compact tissues around the penile portion offers, and the location of the tube here also prevents us from making counter-pressure by proper manipulation which we found so useful in the penile portion.

Except, therefore, in cases in which the stricture is of recent formation, with only a small amount of cicatricial tissue opposite the point, gradual dilatation and pressure will prove, at best, only palliative in strictures of the deep urethra.

Perineal section, or external urethrotomy, is an operation almost entirely void of danger, and, when properly performed, it may always be depended upon permanently to cure strictures in the membranous and bulbous portions of the urethra. It has been so successful in my hands that I have come to feel justified in promising my patients a permanent cure in ten to fourteen days from the date of the operation.

External urethrotomy is free from the dangers and inconsistencies of the internal operation. Its proper performance contemplates and accomplishes the most simple and rational means of relief, which is to incise externally the urethral wall at the point of constriction, and introduce into the incision a wedge of sound tissue sufficiently large to restore the tube to its normal calibre. It is not difficult to accomplish this; my rule is to cut in the centre of the perineum, reach the stricture, freely incise it, cutting into the sound tissues on both sides for a quarter or half an inch; then pass from the meatus to the bladder a hard-rubber catheter of the size of the normal urethra, and tie it in position. This causes a gaping of the walls of the incision, and prevents their primary union, and the extent of this gaping is the correct measure of the wedge of sound tissue which is to be introduced into the circumference of the tube; this wedge is secured by the final union of the granulations, which by thus keeping the walls apart are made to spring up on the two walls of the incision. After thirty-six hours the catheter is removed and the urine allowed to drain from the bladder through the wound, and this, together with the daily passage of a sound of the size of the normal urethra, is sufficient to insure the formation of a proper sized wedge of granulation tissue. Strict asepsis is, of course, observed throughout the operation.

LACERATION OF STENO'S DUCT, FOLLOWED BY INACTIVITY OF THE CORRESPONDING PAROTID GLAND.

By HANS H. SINNÉ, M.D.,
of Trenton, N. J.

Injuries to the parotid gland and its duct are almost invariably followed by disfiguring fistulæ, not to mention more disastrous results. The following case, for singularity of its development and final results, stands probably unique.

On Thursday, April 19th, I was summoned in haste to see Otto F., æt. seven, who, while playing with some comrades, had been thrown upon the ground by a dog, and severely bitten in the cheek.

The tear began at the angle of the mouth, through the more superficial fibres of the sphincter oris, ran thence upward for about an inch in the direction of Steno's duct, and from there in two distinct lines, the lower following the salivary duct to near the lobe of the ear, the other perpendicularly upward to the lower margin of the eye. The intervening tissue of a quarter of an inch in thickness had been torn from the underlying structures, so as to present the form of a flap. Further inspection, upon lifting this flap, revealed the parotid gland uninjured, but Steno's duct was torn at a point very near to the body of the gland. The remnant of this canal, of about one and a quarter inches in length, was found curled up near the angle of the mouth; the intervening piece was missing. The buccal cavity had not been entered.

The wound was washed with warm water to promote bleeding, though nearly an hour had elapsed since the injury was received. This fact and the form of the injury caused me to omit cauterization.

As the remainder of the salivary duct would have been of very little if any use, and lest it might interfere with proper union of the parts, it was removed. The child was put under chloroform, the parts were carefully washed with a warm solution of bichloride, then nicely adjusted and stitched into position. In order to drain any saliva secreted by the parotid gland, several silk threads were put underneath the flap up to the body of the gland. The wound was dressed with iodoform, bichloride gauze, and pressure was exerted upon the gland and flap by a graduated compress, confined *in situ* by an appropriate bandage.

Owing probably to shock and the anæsthetic, there was no secretion of saliva on the injured side for two days. On the third day the secretion of saliva was found resumed, the wound red and angry, several stitches torn out—though due allowance had been made for ensuing tension—and the flow of secretion gravitating toward the lower margin of the wound, and separating its edges, without following the course of the drainage-threads. The exerted pressure had evidently not been sufficient to keep the flow of saliva in the line indicated by the silk drainage.

New drainage-threads were introduced, and, in order to increase the pressure upon the gland and flap from below upward, a broad cork of half an inch in thickness, cut to fit the prominence of the zygomatic arch, and well padded by lint and gauze, was confined underneath the reapplied roller. The cork and bandage were readjusted every day, with the ultimate result that the salivary secretion became greatly diminished, and its flow directed in the course provided for its drainage.

On April 28th the flow of saliva ceased completely. The neighboring submaxillary and sublingual glands and the parotid of the opposite left side showed for a day or two distinct sympathetic disturbance, marked by swelling and pain on pressure. Pressure upon the parts was nevertheless continued.

On May 2d I presented the case to the Mercer County Medical Society, at Trenton, N. J. As there was then no further secretion of saliva, and no serum was visible, and the margins of the wound had become firmly united, pressure by the cork and bandage was discontinued, and, after removal of the now superfluous silk drainage, the wound was dressed with subiodide of bismuth collodion. There has since been no disturbance of any kind, and the wound is completely healed. The boy is still under my surveillance, to guard against accidents.

The dog has unfortunately been shot, against my advice, as I desired to see if any signs of rabies should develop themselves. The animal, though somewhat ferocious, was probably not rabid at the time of the injury.

As there is at present not a sign of either fistula or abscess—complications which I most certainly anticipated—I can but conclude that the parotid gland, owing to the continued pressure, became hermetically sealed by the union of the flap to the underlying part, and ceased activity, in time probably undergoing atrophy because of non-use.

The patient does not complain of pain or other ailment, and is to all appearances perfectly well. The case in question certainly compels us to conclude that it is best to postpone surgical interference in all similar cases *ad ultimum*.

145 BUTLER ST., May 7, 1888.

MEDICAL PROGRESS.

The Diagnosis of Syringomyelia.—At a meeting of the Verein Deutscher Aertzte in Prague, held January 13, 1888, PROF. KOHLER made some remarks on the diagnosis of syringomyelia.

The patient exhibited showed, besides progressive muscular atrophy of both upper extremities, in course of development for three years, an affection of the skin, limited to the region of the shoulder and arm, consisting in numerous circumscribed spots of necrosis, with succeeding ulceration and keloid cicatrization. Besides, there exist defects of the temperature sense in both hands and on the left forearm; and upon both sides, the oculo-pupillary symptoms of paralysis of the cervical sympathetic.

The preceding complexus of symptoms may depend upon two conditions, that of the formation of a cavity dependent upon dilatation of the central canal, and that of central glioma of the spinal marrow, the latter with or without the formation of a cavity and fissure.

Both the processes mentioned, at the time, were not susceptible of differential diagnosis. The central seat of the changes, and the preference with which the cervical cord is first attacked, are common to both. He made a searching analysis of the complexus of symptoms hitherto observed in the cases of syringomyelia referred to, and gives prominence to the following signs, as of diagnostic significance by reason of their peculiarity, or of their association: the progressive muscular atrophy, peculiar disturbances of sensibility, particularly analgesia and defects of the temperature sense, finally trophic disturbances of the skin and deeper parts. The last may appear as paronychia, leading to the loss or deformity of individual phalanges of the fingers, or as a deep-seated phlegmonous inflammation. Or they may show them-

selves, as in the patient presented, upon the skin in the form of vesicles, which appear filled with serous or purulent contents, and change to protractedly suppurating ulcers, on which an indurated cicatrix is frequently to be observed. Or, finally, there occur in the cases of such patients, spontaneous, or rather, upon slight cause, fractures—the so-called spontaneous fractures. It is worthy of notice that any of the manifestations of the disease may appear as the first symptom, and for a time may exist alone. In the progress of the case, regular combinations of various kinds occur, and, finally, depending upon the extension of the process in the soft substance of the spinal marrow, spastic paresis and paraplegia of the lower extremities associate themselves. The oculo-pupillary symptoms are also dependent upon the disorder of the cervical muscles, and may be of diagnostic importance in a given case.

Prof. Chiari spoke of the pathological anatomy of syringomyelia, a name at the present time generally appled to every protracted cavity formation in the spinal marrow in adults. Surely the individual cases, as a careful analysis of respective reports shows, are generically widely different, as cavity formations in the spinal marrow in adults may result from gliomatous degeneration, from the persistence and progressive development of congenital anomalies of the central canal, from circulatory disturbances in the spinal cord, from myelitic softening and also, as Chiari, in a recent case, had the opportunity of confirming, from hyperplasia of the central connective tissue, with transudation into the previously normal central canal. Chiari, therefore, suggested that all cavities in the spinal cord associated with the central canal, be called hydromyelia, and that the termination "syringomyelia" be reserved for those not so associated.—*Deutsche med. Wochenschrift*, May 24, 1888.

A Case of Subcranial Hemorrhage treated by Secondary Trephining.—W. Thornley Stoker, in the *Annals of Surgery* for June, 1888, reports the case of a laborer, aged fifty, who had been rendered insensible by a fall from a cart. There was more or less complete left-sided paralysis, but no disturbance of sensation. The pupils were but slightly affected, the breathing was slow and stertorous, and the temperature and pulse above the normal. A bruise was found on the right side of the cranium, about one inch from the middle line, on that part of the scalp corresponding to the upper part of the fissure of Rolando. On the ninth day after the accident a trephine was applied, with antiseptic precautions, and a well-formed blood-clot between the bone and dura mater removed. Signs of returning brain power at once showed themselves, and the patient made an uninterrupted, good recovery.

The writer comes to the conclusion that in cases of intracranial injury involved in doubt we should operate, so long as evidence of such constitutional disease or local condition as points to apoplexy is absent.

Experimental and Clinical Contributions on the Action of Cocaine.—Rosenthal (*Wiener med. Wochenschrift*, 1888, No. 5) believes that the manifestations of increased arterial tension, and the central or local effect of the anæsthesia produced by cocaine, may be applied to the treatment of some symptoms of nervous disease and other organic affections. The methodical use of the drug in the depressive form of neurasthenia, by increasing the arterial tension, caused amelioration of the nervous symptoms. Increasing doses (⅓–½ gr. twice a day), given for weeks, relieved the abnormal impressibility, as well as the feeling of dread, produced a slight intoxication, cheerfulness and hopefulness, and gave the patient a fresher appearance, fuller pulse, better arterial tension of the radial, greater activity and stimulation of the mental functions.

Its action in some cases of tabes dorsalis was even more marked; the influence upon the frequent lancinating pains was most favorable. If a 3 per cent. solution were injected hypodermatically as soon as the neuralgic paroxysm manifested itself by circumscribed burning of the skin or hyperalgesia, subjective feeling of cold, paleness of surface, as well as weak and small pulse, in ten or fifteen minutes a feeling of bodily warmth returned, the circumscribed hyperæsthesia disappeared, the skin regained its redness and moisture, and the radial pulse became noticeably fuller and tenser, and in a half hour to an hour the patients could leave their beds. Corresponding injections of morphine, napelline and antipyrin failed to afford similar good results. Not only was their calmative influence less speedy than in the case of cocaine, but their use was also attended with a longer, more unpleasant and more general depression. On the other hand, the continued use of cocaine gradually makes more concentrated solutions (up to 5 per cent.) necessary, and frequently gives rise to unpleasant sensations in the stomach, lasting for hours, for which a little cognac was used and seemed effective.

In chronic diseases associated with dropsy, injections of ½ grain diminished the œdema, it is true, only during the time of their use, probably by increasing the intrarenal pressure and the action of the heart.

The anæsthesia of cocaine may be made operative centrally or peripherally. Marked improvement in the boulimia (hyperorexia) dependent upon hyperæsthesia of the gastric vagus centres was noticed from the protracted use of 1/6 to ⅓ grain (twice or three times a day). In various forms of nervous cardialgia good results were noted when cocaine was given at the beginning of the attack, best in a solution of 2 to 3 grains to 5 ounces of water, a teaspoonful every fifteen minutes until the cramps were allayed.

As disease of the vagus nucleus has recently been repeatedly demonstrated in spinal cardialgias, Rosenthal believes that in the gastralgias occurring with severe emotional disturbances, in hysteria and neurasthenia, there is not stimulation of the terminal filaments of the sensory nerves in the stomach, but irritation of the bulbar vagus centres, and, as a result of his experience, recommends cocaine as particularly soothing for the excentric irritation.

In anorexia nervosa, due to a hyperæsthesia of the peripheral gastric nerves, with oppression and pain following every meal, cocaine given in the manner indicated before the meal, ought to repress the unpleasant sensations; just as, according to Weiss of Prague, the vomiting of pregnancy, even in severe forms, may be relieved by the administration of cocaine, 3 grains to 5 ounces of water, a dessertspoonful every half hour.

For the peripheral colicky pains in nervous, anæmic persons and those addicted to the morphine habit, cocaine, given in the manner indicated, does good

service; and in these cases the painful excitation of the special ganglionic apparatus in the wall of the intestine, which controls the intestinal movements, appears to be allayed in a manner similar to that in which the irritated gastric nerves are affected. Finally, the hyperæsthesias of the urethra and neck of the bladder in cases of neurasthenia sexualis, in nervous spermatorrhœa, or in consequence of persistent pollutions or excesses, are favorably influenced by weak, local injections, and allow of the methodical use of the bougie; as well as combination with rational hydraulic treatment, in order to overcome the obstinacy of the disorder. In conclusion, Rosenthal states that the annoying tinnitus aurium from the use of quinine or salicylic acid may be lessened by the addition of a small quantity of cocaine (1/6 gr. to 15 grains). —*Therapeutische Monatshefte*, May, 1888.

For Neuralgia.—Dr. B. W. Richardson recommends (*Asclepiad*, No. 18) the following formula in neuralgia:

R.—Croton chloral	gr. ij.
Quinia	gr. ij.
Glycerin	q. s.

To make a pill; to be taken when the attack threatens, and to be repeated every two hours until relief is obtained.

The Treatment of Excessive Perspiration.—Bardet, in excessive and odorous perspiration in the feet or axillæ, combines with bathing and the application of alcohol the use of the following powders:

French chalk (Talc)	40 parts.
Subnitrate of bismuth	45 "
Permanganate of potassium	13 "
Salicylate of sodium	2 "

To be finely pulverized.

Rice powder may be used in the following combination:

Rice powder	60 parts.
Subnitrate of bismuth	25 "
Permanganate of potassium	10 "
Powdered French chalk (Talc)	5 "

To be thoroughly mixed, and finely powdered.—*Les Nouveaux Remèdes*, May 8, 1888.

The Treatment of Furuncles of the Ear with Alum.—Grasch reports good results from the use of alum in solution in furuncles in and about the ear. Pain was speedily relieved, suppuration was checked, and permanent recovery followed. — *Berliner klinische Wochenschrift*, No. 18, 1888.

Sabre-cut upon the Skull, with Indication for Trephining.—At a meeting of the Vienna Society of Physicians on May 11, 1888, Nothnagel exhibited a girl aged eighteen, who nearly a year previous had received a sabre-cut from behind on the head, knocking her senseless. Half an hour later, when consciousness returned, paralysis of the right arm and leg, and diminished sensation, were present. The paralysis gradually disappeared, and the wound healed. Fourteen days after the healing of the wound convulsions occurred in the right leg, which were present when the patient was exhibited. The upper extremity remained normal, the lower was paretic; the convulsions consisted of clonic spasms, rapidly following each other, and persisting for one or two minutes; there was no disturbance of sensation, but the muscle sense was impaired. The scar, four inches long, indicated the location of the lesion in the brain, at the upper extremity of the central convolution. The process going on Nothnagel diagnosed as a chronic disturbance of function of this region, or the periodic action of an irritant. The formation of osteophytes on the periosteum or pachymeningitis he considered the probable condition present. The treatment indicated is surgical interference, which offers an excellent chance of perfect recovery.—*Wiener medizinische Presse*, No. 20, 1888.

Atheroma of the Kidney.—In the *Archiv für klin. Chirurgie*, Bd. 36, S. 304, Schlegtendal reports a case of true, congenital calcareous atheroma of the kidney, in a man of twenty-two, found at the autopsy. The case is unique, as but one specimen of atheroma of the kidney (Museum of the College of Surgeons, New York, 1904) is mentioned by Paget.—*Fortschritte der Medicin*, June 1, 1888.

A Case of Extirpation of the Spleen.—Prof. C. Liebman, of Triest, in the *Centralblatt für Gynäkologie* of May 26, 1888, reports the case of a peasant, aged twenty-eight, who had never suffered from any grave disorder or intermittent fever. Since her second confinement, in May, 1885, she noticed a hard swelling to the left of and below the umbilicus, which for a long time remained stationary, and at first caused no discomfort. About five months before admission into the hospital, the swelling began to grow and became so troublesome that she was incapacitated for work, and asked for the removal of the tumor.

On the 25th of November, 1887, the patient was found pale and weak, with anæmic mucous membranes. Nothing abnormal was found in the chest. Liver dulness normal. The splenic outline was evident to the eye, and extended in the axillary line from the eighth to the tenth rib, with a longitudinal measurement of about two and three-quarters inches. The abdomen was enlarged by an ovoidal tumor, of the size of an adult's head, with a smooth surface, somewhat depressed in the middle, resting in the pelvic inlet, rather more to the left of the middle line. The tumor was evidently intraperitoneal, movable in all directions, and could be brought to the margin of the ribs on both sides, but not beneath them. The abdominal walls could be moved upon the tumor without friction sound. Distinct systolic blowing sounds could be heard over the tumor. The uterus was normally mobile, slightly retroverted; the left ovary could be distinctly felt, the right not. The uterus followed the lateral movements of the tumor, in so far that when the tumor was moved toward the right, the fundus uteri was distinctly pushed to the same side; on the contrary, the uterus scarcely moved when the tumor was drawn to the left. Raising the tumor, the uterus remained in place. Urine was quantitatively and qualitatively normal. Appetite moderate; digestion good.

The diagnosis of a neoplasm of the peritoneum, or of the ovary, was made, and the menstrual period was awaited for the performance of laparotomy.

The operation was performed on the 13th of December. An incision about seven inches long, was made in the

linea alba. The great omentum exhibited enormously enlarged vessels, and entirely covered the accessible portion of the tumor. The hand was inserted into the abdominal cavity, and the uterus and atrophied ovaries found to have no connection with the tumor. The latter was easily removed, and proved to be the spleen, enlarged to about four times the normal size, its convex surface directed forward; the suspensory ligament of the spleen was tied with two ligatures. The hilus, of the thickness of the little finger, was divided by the blunt director into three parts (the middle containing the artery), and each mass tied separately; three-fourths of an inch toward the median line a single ligature was applied to the whole, another close to the spleen, and then the hilus was severed with scissors. The operation did not last long, and the loss of blood was slight.

The removed spleen, drained of blood, weighed 22.18 ounces, was 7.08 inches long, 3.93 inches wide, of homogeneous, firm texture.

The progress of the case was good, and the bandage was removed on the eighth day. The abdominal wound was completely healed by first intention. On December 21st, menstruation commenced, with dragging pains in the lateral abdominal regions, particularly on the left. On the second day of the menstrual period, the temperature suddenly rose to 105.2°; the pains became very severe, and an exudation to the left of the uterus could be detected. The exudate grew rapidly in the course of the following days. The high degree of anæmia, the rapid development of the exudation, its doughy consistence excited the suspicion that the parametritis was possibly hemorrhagic. As fluctuation could not be detected, treatment was expectant (quinine, antipyrin, tonics, ice-bags). The exudation then gradually diminished, and, after a month, was markedly reduced in size. The anæmia also improved. In a few weeks the patient was considered as completely cured, and, on the 28th of March, discharged.

Unfortunately, the blood was not examined prior to the operation. One hour after, however, with repeated comparative examinations, the white corpuscles were found increased seven-fold. In the course of convalescence, the leucocytes did not increase, so that, in this case, the influence of the extirpation of the spleen upon the increase of white corpuscles failed of demonstration. With the progress of convalescence, and with the strengthening of the patient, the number of white corpuscles naturally diminished, and upon the discharge of the patient only slightly exceeded the normal. During the whole time, enlargement of neither the thyroid gland nor of the lymphatic glands was observed.

Subsequent, repeated examinations by different colleagues confirmed the strange fact that the apparent splenic dulness was very varying; at times, it was very evident; at other times again, less marked, and, now and then, hardly detectable. Nor was its outline constant; at times it appeared larger, at other times smaller, and had a changing shape; in other respects, the dulness was normal, descending one intercostal space with full inspiration. Liebman explains this by the presence of fecal masses filling the left flexure of the colon.

Leaving out the cases of partial or complete extirpation of the spleen after injuries to the organ, as far as the author can learn from the accessible literature, there have been forty-six instances of extirpation of the spleen (the two of Zaccarelli and Ferrerius, cited by Credé, in Langenbeck's *Archiv*, Bd. xxviii. S. 404, cannot be counted), with only fifteen recoveries. The apparently high mortality is explained by the fact that the operation was performed eighteen times for leukæmia, and all of these cases speedily terminated fatally. Thus, the fifteen recoveries are to be considered in connection with the remaining twenty-eight cases, in which the operation was performed for the most varying indications. If it be remembered that many of the operations belong to pre-antiseptic days, the mortality may be viewed as still less high.

Particularly fortunate were the results of extirpations of wandering spleens. The author is familiar with ten such operations (including his own), with eight recoveries: one each by Czerny and Martin, in Germany; Polk, Nilsen and Leonard, in America; Thornton, in England; and Ceci, Urbinati and Aonzo, in Italy. Only two were fatal. In Urbinati's case, the progress was favorable until the fourth day, when death occurred almost suddenly from twisting of the stomach, enormously distended with gas. At the autopsy there was no sign of hemorrhage or of peritonitis. The extirpation of the spleen *per se* was not the cause of the fatal issue. The woman operated on by Aonzo died in three hours, of shock; the splenic tumor weighing, without blood, 144.66 ounces.

It is not to be conceived why the extirpation of a floating spleen should have a worse prognosis than the removal of an ovarian tumor, when, on the one hand, it is considered that splenectomy, of itself, is not more difficult nor more dangerous than ovariotomy; and, on the other, that the animal economy suffers no particular injury in the ablation of the spleen, as the many experiments upon animals, the cases of loss of the spleen after injuries, and the as yet few successfully conducted extirpations prove.

Glycerin Suppositories for Habitual Constipation.—BOAS, in the *Deutsche medizin. Wochenschr.* of June 7, 1888, states that in a large number of cases he has had good results from the use of glycerin enemata as a purgative; but in some cases, particularly those with hemorrhoids, or in individuals with an irritable rectal mucous membrane, which readily bleeds, the use of the syringe is no slight objection, so that the injections must be intermitted or entirely refrained from. The use of the syringe is also inconvenient. For these reasons he has had prepared suppositories consisting of capsules containing 16 minims of pure glycerin, which he has used in twenty cases, with the best results. The suppositories have been found to retain their form and efficacy for many weeks. Fifteen to twenty minutes after using one there is a desire to go to stool, but without tenesmus or other discomfort; soon followed, as a rule, by a copious evacuation. The employment of glycerin per rectum seems specially indicated when, with the constipation, there exists gastric disorder.

Anthrarobin: a Substitute for Chrysarobin.—DR. BEHREND (*Viertl. f. Derm. u. Syph.*, 1888, 2 Heft, S. 261) has made experiments with a substance discovered by Professor Liebermann, of Berlin, named anthrarobin, which has an analogous action to that of chrysarobin and pyrogallic acid, being less active than the former and more active than the latter. It produces less inflammatory irritation than chrysarobin, and does not present

the dangers of absorption which attach to pyrogallic acid. In dispensing, it requires to be rubbed up with olive oil before being mixed with the ointment basis. Ten and twenty per cent. ointments are used. Although it is insoluble in water, it becomes soluble by the addition of borax, and is also very soluble in alcohol and glycerin. Anthrarobin 10, borax 8, distilled water 80, is one formula; anthrarobin 20, borax 35, alcohol and glycerin each 90, is another formula. Anthrarobin stains the skin and linen, although not so intensely as chrysarobin, and so little irritation does it produce that it may be applied to the head and face, and even to the eyelids. The alcoholic tincture is preferred to the ointment, and the action of this substance is much increased if the part is washed with soap, particularly with potash soap, before it is used. It acted successfully in cases of psoriasis and erythrasma. It cures psoriasis less quickly than chrysarobin, but more quickly than pyrogallic acid.—*British Medical Journal*, June 9, 1888.

Laparotomy in Tubercular Peritonitis.—Of fifty-four cases of laparotomy in tubercular peritonitis collected by TRZEBICKY (*Wiener medizin. Wochenschr.*), four died from the immediate consequences of the operation, while in a fifth, death occurred, soon after the operation, from acute miliary tuberculosis, though the fluid had not reaccumulated. One case died, in four months, of general tuberculosis, without the peritonitis disappearing. Cures resulted in forty cases, though, here and there, advance of pulmonary tuberculosis was reported. The majority of cases were in females, which may find its explanation in the fact that most were operated upon under an error in the diagnosis of ovarian cyst. The statistics are yet too meagre, the correctness of the diagnosis not entirely above doubt, and the period of observation after operation not long enough; but, in view of the results, there is no longer any justification for expectant treatment. Even though, in some cases, recovery was not permanent, the fluid did not reaccumulate, and the patients were relieved of their distress. Spontaneous recovery from tubercular peritonitis is exceptional; and operative interference is indicated the more, as it would seem that, in many cases, tuberculosis of the peritoneum is a primary affection, and the source of general infection.

As all other therapeutical measures are futile in such cases, and laparotomy, under antiseptic principles, may be considered free from danger, the operation is certainly indicated. It consists in a free incision, and thorough evacuation of the fluid.—*Memorabilien*, May 31, 1888, from *Centralblatt f. d. ges. Therap.*, 1888.

A Rare Form of Quinine Eruption.—WERNER, of Markgröningen, relates the case of a woman aged fifty-nine years, who took six grains of quinine daily for headache, tinnitus aurium and vertigo. After the second grain, she had chills, and, during the night, pains in the joints of the hand and fingers. The fingers were uniformly yellowish-red, without swelling, and numb. Withdrawing the quinine, in three days the redness and all abnormal condition had disappeared. When twenty-four, the patient had a "sort of intermittent fever," for which she took quinine, without particular effect, but without any other manifestations. A year and a half later, taking quinine for facial neuralgia, large and small red spots with vesicles at once appeared all over body, particularly at the joints of the upper extremity, which disappeared on the following day. Shortly after this she suffered with angina Ludovici. During convalescence, quinine was ordered, and, after the second dose, a red, burning eruption appeared in the neighborhood of the site of the operation. Eleven years later, one hour after taking quinine again for a facial neuralgia, she had rigors and an eruption on the arms.—*Therap. Monatshefte*, March, 1888, from *Würtemb. Corr. Bl.*, 1888, No. 5, p. 35).

Codeine to Relieve Abdominal Pains.—DR. LAUDER BRUNTON states (*British Medical Journal*, June 9, 1888) that the results he has obtained from the administration of codeine have satisfied him that it has a powerful action in allaying abdominal pain, and it can be pushed to a much greater extent than morphine without causing drowsiness or interfering with the respiration or with the action of the bowels. It is, therefore, specially indicated where a dilated heart and consolidated lung tend to make one afraid of morphine. Codeine is also specially indicated where one wishes to relieve the pain without interfering with the action of the bowels. On the other hand, in cases in which there has been much diarrhœa, as in some cases of malignant disease of the colon or rectum, the absence of any tendency to lessen peristaltic movement is rather a disadvantage to codeine as compared with morphine or opium.

He has found that in cases of long-continued enteralgia without organic disease, it has continued to relieve pain for months together, without the dose being increased beyond one grain three times a day, and he found the same to be the case where the presence of a tumor, in addition to other symptoms, had led to the diagnosis of malignant disease.

The Treatment of Round Ulcer of the Stomach.—GERHARDT writes that dietetic treatment is the basis of all proper treatment in these cases; milk diet is most suitable for recent cases; peptones should be given preferably by enemata, as they often irritate the stomach. In hemorrhage and peritonitis enemata only should be given. Morphine should be used as little as possible. Chloride of iron should be prescribed when possible; the weak alkaline waters should be used (Carlsbad) except in very anæmic patients. Washing out the stomach should only be employed in recent cases, as the weakened stomach walls may rupture in old ulcers. In persistent pain in an empty stomach nitrate of silver is indicated. Condurango is an excellent tonic in old ulcers of the stomach. A gastric ulcer may be considered healed when the patient gains in weight, when gastric pains cease and when no sensitiveness on pressure exists over the epigastrium.—*Berliner klinische Wochenschrift*, May 7, 1888.

The Subcutaneous Injection of Antipyrin.—WOLFF, of Breslau (*Therap. Monatshefte*, June, 1888), thus summarizes the uses of antipyrin subcutaneously: 1. In muscular rheumatism. 2. For the chest pains of phthisis. 3. For the neuralgias of superficial nerves. 4. As an aid in diagnosis. 5. In attacks of asthma. 6. For painful conditions, when morphine is contraindicated, or to replace the latter, particularly in children and those who bear morphine badly.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 14, 1888.

THE CAUSES OF PUERPERAL INFECTIOUS DISEASES.

AFTER the doctrine of the infectious nature of puerperal fever had been generally accepted, efforts were, of course, made to discover the ultimate cause. Especially did the youthful science of bacteriology give great impetus to such investigations. Though the results were fruitful, in so far as finding germs was concerned, yet they seemed to do little more than confirm what clinical experience had taught, namely, that the disease was not always due to the same cause. And just as erysipelas, sepsis, diphtheria and some other usually surgical diseases were looked on as the foci of infection, so, in later researches, the streptococcus pyogenes or that of erysipelas or sepsis or diphtheria was found in the lesions of those who succumbed to childbed fever.

But, while the diseases named were and are clearly distinguishable, their minute causes are by no means so. Microörganisms of the genus streptococcus are found as causes in erysipelas, phlegmon and some septic diseases, and as an accidental occurrence in diphtheria, in five conditions, which have many striking resemblances to each other. In appearance and mode of growth, they vary so little, that the points of difference are believed by many to be caused by variations in the nutriment. Inoculations show some, though slight, difference of action. The thought was, therefore, very near to consider them as identical, and assume that the resulting form of disease owed its type to some peculiarity, variable or constant, of the individual. Or, it was urged, that the species underwent "variations," a view advocated with enthusiasm by bacteriologists with evolution theories fresh in their minds.

VIDAL has reported to the Academie de Médecine de Paris the results of his studies of the "forme septicémique pure" in puerperal fever, or typhoid type without suppuration (*Gaz. hebdom.*, No. 22, 1888). In all of his cases, he found the streptococcus pyogenes, and from this and the result of his culture and inoculation experiments, he comes to the conclusion that it is impossible, in the present state of our knowledge, to distinguish between the various forms of streptococci, and that one and the same form can set up any of the various forms of puerperal infection. In all of these conclusions, he is confirmed by DOYEN and by ARLOING (*L'Union méd.*, No. 74, 1888).

This is strong evidence, though it will require a much larger consensus of public opinion to settle definitely the questions as to the various kinds of streptococci, as well as the affections caused by them.

It is highly probable that many cases of puerperal fever, especially of the septicæmic type, are cases of mixed infection by putrefactive bacteria, and that to these are due the symptoms of intoxication by ptomaines, which distinguish some cases.

Practically, the unity or variety of the coccus is of no importance. Anti-bacterial remedies are no more potent against one form than another, and safety is only assured when all possible sources of infection are kept far away from the favorable soil offered by the *post-partum* genitals.

A STATUE TO THE PHYSICIAN-PATRIOT, BARTLETT.

ON the Fourth of July, at Amesbury, Mass., a handsome bronze statue of DR. JOSIAH BARTLETT, the revolutionary statesman, was unveiled; and the occasion was rendered memorable by a poem contributed by the poet Whittier.

Bartlett was born in Massachusetts, and there obtained his classical and professional training, but at the age of twenty-one he removed to New Hampshire, with which State his fame will ever be identified. For fifteen years he devoted himself earnestly and intelligently to medical practice, and acquired eminence therein; but in 1765 he became a delegate to the Provincial Assembly, and from that time on-

ward, for a period of thirty years, his activities were almost exclusively absorbed in public affairs. He was an ardent patriot—as were nearly all the doctors of his time, although, in the beginning, he was courted by the royalists on account of his commanding abilities and popularity.

He was born for leadership, and he had all the heroic qualities that made him worthy to participate in the stirring events of the revolutionary period. He was a member of Congress on that eventful July day, when the roll was called, with Bartlett's name the first upon the list, and he voted "with bold and unwavering voice" to declare the independence of the colonies. As a signer of the Declaration his name is immortalized and stands second, that of Hancock, the President of the Congress, alone preceding it. He also, for his State, subscribed to the Confederation of 1778, in the forming of which he assisted. He carried a sword into the field, and was present under Stark at the fight at Bennington. After the peace, he was elected to many of the highest offices in the gift of people; he was Chief Justice, and Governor, and Senator-elect to Congress.

To Bartlett, as the patriot and statesman, it is fitting that such honor as the sculptor and poet can accord should be given. Of Bartlett, as a physician, comparatively little is known, except that he appears to have been both scholarly and independent. It is said that he favored the use of Peruvian bark in malignant sore throat, epidemic during his time, and in some other conditions in which its employment was frowned upon by the profession of that day; and that he was one of the founders of the Medical Society of New Hampshire, and was its first President from 1791 to 1793.

In addition to Bartlett, four other physicians have the undying honor of having been signers of the Declaration of Independence, namely, Benjamin Rush, Matthew Thornton, Oliver Wolcott and Lyman Hall.

HOSPITALS ON THE HIGH SEAS.

A proposition has been made by the *Lancet* in favor of fitting out ships for the accommodation of phthisical patients and of convalescents generally, with the object in view of supplying these cases with the purest of sea air. These vessels, it is recommended, will cruise within easy reach of such ports as will afford them fresh vegetables and water; and, according to the season, they will sail either in southern or northern waters. They will have a staff of efficient medical officers; and every appliance and means of treatment will be provided.

There are very many persons who, with ample means at their command, are suffering from lung-hunger and lung-thirst and might regain their lost health if they could, in some manner, get access to the limitless supplies of fresh and pure ocean air, for the like of which they pant at home. It is claimed for the cruising ocean hospital that it will combine certain advantages which are sought to be obtained, but not always with success, by the construction of sanitariums at great elevations to provide phthisical and other invalids with an abacterial air; more especially will it enable a change of location at the bidding of the seasons; it will bring its inmates into contact with air that is salt—and tonic, on that account, to a large proportion of respiratory patients, and not unduly rarefied, and it will avoid some of those excessive fluctuations as to the humidity and temperature of the air that are experienced at some of our land health resorts.

The Massachusetts Medical Society having found that the essays placed in competition for the Shattuck Prize were rarely worthy of the prize, which, on the last occasion, amounted to one thousand dollars, has decided to divert the fund to the purposes of a "Shattuck Lecture" to be given on some subject in accordance with the original provisions of the bequest. The lecture is to be delivered at the annual meeting of the Society, and the honorarium for it and its publication are to be defrayed from the income of the Shattuck Fund.

A very unusual event is the governmental suppression of a medical journal, which has recently taken place at Cairo, Egypt, in consequence, it is alleged, of an article upon Asiatic cholera and the necessity of a rigid quarantine of all vessels from Indian ports. The journal in question was a struggling little periodical, published in Arabic, and called the *Shifa*.

The event is described in a letter by Dr. Grant-Bey to the *Albany Medical Annals* for June, in which he states that he was the author of the obnoxious article, and that strong views in favor of a genuine quarantine against cholera are regarded as highly injurious to the trade interests of England, and that for this cause the little *Shifa* was smothered by the authorities. Dr. Grant-Bey also says that the offending article was in part undertaken and written

for the *Shifa* in order to describe to the native physicians a visit made to him by Virchow, who was at that time in Egypt with the explorer Schliemann, and who, on all suitable occasions, sought to impress upon the Egyptians the importance of hygiene and of adopting modern sanitary methods. This, moreover, we learn from the London *Lancet*, was the theme of Prof. Virchow in an address before the Medical Society in Cairo, newly organized under the presidency of Dr. Salem Pacha.

THE American Otological Society will hold its twenty-first annual meeting at the Pequot House, New London, next Tuesday, and on the following Wednesday and Thursday, July 18th and 19th, the American Ophthalmological Society will hold its twenty-fourth annual session at the same place.

THE thirty-sixth annual meeting of the American Pharmaceutical Association will be held at Detroit on September 3d.

THE faculty of the New York Polyclinic have decided to increase the clinical facilities of that Institution by establishing a spacious hospital immediately connected with the college building. It will be opened for the reception of patients in October next.

THE eighth annual meeting of the Lehigh Valley Medical Association will be held at Paxinosa Inn, near Easton, on Wednesday, August 15th.

THE "Société d'Ophthalmologie de Paris" was organized at Paris on June 12th. It is an association of ophthalmologists, to which only Frenchmen are eligible to membership, but which will receive and discuss communications from specialists of all countries. For 1888, Chevallereau is President, Chauvel Vice-President and Gorecki Secretary.

SCANZONI has resigned his position as instructor at Würzburg. The authorities have conferred upon him the honorary privileges of citizenship.

THE Seventh International Ophthalmological Congress will be held at Heidelberg, August 8th to 11th, and a number of American ophthalmologists have gone abroad to participate in its proceedings.

A HYGIENIC Exposition will be opened at the Industrial Palace, in Paris, on July 20th. Among the members of the committee in charge are Berthelot, Larrey, Dujardin-Beaumetz and Monin.

PROF. ADAMKIEWICZ has resigned his chair at Cracow, to reside at Berlin.

PROF. LEUTHOLD, of Berlin, has been made body physician to the Emperor William.

THERE are 4767 attendants at the current session of the Berlin University.

REVIEWS.

OPHTHALMIC SURGERY. By ROBERT BRUDENELL CARTER, F.R.C.S., Ophthalmic Surgeon to St. George's Hospital, etc.; and WILLIAM ADAMS FROST, F.R.C.S., Assistant Ophthalmic Surgeon to St. George's Hospital, etc. Illustrated with a chromograph and 91 engravings. 12mo. pp. 554. Philadelphia: Lea Brothers & Co., 1888.

IN joint authorship it is common for the senior, or more widely known associate, to lend his counsel and the prestige of his name; while the junior writes the bulk of the book. But in this case the custom has been honored in the breach. To each chapter are appended the initials of the writer; and we find, of fifteen chapters, eight, including 282 pages, are signed R. B. C.; while seven, covering 250 pages, are from W. A. F.; and the literary style of the different chapters attests the truth of the signatures. In the division of subjects, most writers would think that Carter had had the first choice, his including anatomy and physiology, examination of the eye, diseases of the cornea, sclera, iris, the lenticular system, optic disk, retina and choroid, glaucoma, amblyopia, and amaurosis. Still Frost, among affections of the eyelids, lachrymal apparatus, and conjunctiva, the vitreous, ocular muscles, and orbit, injuries, errors of refraction, and color vision and its defects, finds some subjects that he is especially competent to discuss, his account of the refraction of the eye and its anomalies being particularly good.

The work contains nothing of importance that is entirely new to the literature of ophthalmology. But there are many things to be found in the current periodical literature, which have not, heretofore, found place in the text-books. Matters like the omission of iridectomy, or of subsequent bandaging, in cataract extraction; the use of passive motion in ocular palsies; the new substitutes for enucleation; the appearances of air bubbles in the vitreous; the recent scepticism as to *amblyopia ex anopsia*, are all mentioned, although on most of these points the writers express rather conservative views. And, what is almost unique in a book of European authorship, the writings of American ophthalmologists are very fairly treated.

The chapter headed "Anatomy and Physiology" might, with equal propriety, have been headed Diagnosis; for it is devoted mainly to that most important branch of diagnosis—the differentiation of morbid from normal

phenomena, and the anatomical and physiological explanation of symptoms. The facts, well presented in this and the succeeding chapter, on the Examination of the Eye, should be familiar to every general practitioner of medicine.

Mr. Carter well urges, as the first canon in the treatment of keratitis, or iritis, "the negative one to do no mischief;" and he supports it with an interesting experience of the bad effects of irritant (so-called astringent) collyria in the latter affection. What is said of irritants in keratitis is also good. But he does not sufficiently bring out the fact that obstinate inflammation of the cornea is very often dependent on inflammation of the conjunctiva lining the lids; and while it is very important to keep silver nitrate or copper sulphate off the cornea, to effect a cure, it is equally important to apply them regularly and effectively to the surface of the everted lids.

In appendices are given specimens of Snellen's distance test-types, reading types after Jäger, the groups of dots used for testing vision in the army, and formulæ. Among the latter we note that for a solution of homatropine hydrobromate, six grains to the fluidounce, not strong enough to be relied on to paralyze the accommodation. While of boric acid, which, in powder, produces no marked effect when dusted on the conjunctiva, a solution of four grains in the fluidounce of water, is spoken of as "a mild astringent for conjunctivitis." This suggests the question, Do we sufficiently appreciate the "astringent" properties of pure water?

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, June 13, 1888.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. William H. Parish read a paper on

THE MANAGEMENT OF DELIVERY PRIOR TO THE SEVENTH LUNAR MONTH.

In the management of delivery prior to the seventh lunar month, he said, the welfare of the mother is alone considered. The non-viability of the embryo or fœtus removes it beyond consideration. It is true that the question as to whether the threatened abortion or miscarriage is inevitable or not will frequently arise, and will challenge most anxious study, for upon the continuance of the pregnancy hangs the life of the intrauterine being if it is still living. His purpose, however, in this brief communication was to discuss the management of only the inevitable deliveries prior to the viability of the offspring, and not to treat *in extenso* of any other part of the general topic of abortion or miscarriage.

Delivery during the early weeks of pregnancy is attended with a minimum of risk to life, yet subinvolution, often with endometritis and endosalpingitis, frequently follows such an abortion. About the third month, begins the actual danger of death from hemorrhage and septicæmia, and this danger increases as the period of pregnancy at which delivery occurs advances, up to the time when viability of the child begins and the phenomena of labor at full time more or less pertain. It should be borne in mind that crippling of the functional sexual capacity of the woman is liable to result whatever the period of non-viable delivery.

The treatment of such a delivery is divisible into the expectant and the active plans. The chief difference between these two plans consists, on the one hand, in securing artificially the emptying of the uterus if nature does not effect this promptly, while, on the other hand, such interference is strictly avoided, at least until symptoms determine danger to the patient. During the early weeks, there not arising practically any danger of loss of life, the plan of non-interference is not departed from by its advocates, and is adopted by not a few of those who resort to the more active treatment in the more advanced deliveries.

In early abortions, say prior to the end of the second month, in addition to rest for eight or ten days in bed or on the lounge, he has practised during late years antiseptic cleansing of the uterine cavity by means of one injection of a corrosive sublimate solution 1 to 4000; after the escape of the ovum he resorts to only one injection and always uses a return-tube catheter. He has not thought it necessary to resort to the curette prior to the second month, except when by reason of instrumental interference septic infection is especially liable. During the third month, in addition to the antiseptic intrauterine injection, he uses a smooth wire curette, preferably immediately after the escape of the ovum, resorting at the same time to the injection. It is during and after the third month that dangerous hemorrhage may arise. If the patient is confined to the recumbent posture, danger from this source, however, rarely occurs. If the bleeding appears, however, before the os is sufficiently dilated to admit of emptying the uterus, he tampons both the cervical canal and the upper vagina. For this purpose he prefers strips of baked cloth, because of the ease of introduction and of removal. Antiseptic syringing is resorted to both before the introduction and after the removal of the tampons. The tampon should not be resorted to as a routine treatment. Hemorrhage that is not controlled by the postural treatment and by cold applications is the only indication for the tampon. After the os is dilated, the best way of treating the hemorrhage is to empty the uterus and to inject into its cavity hot antiseptic water.

In the absence of serious hemorrhage, the rule to avoid rupturing the membranes should be rigidly adhered to, inasmuch as an unbroken ovum tends to prevent or to check hemorrhage, and if the ovum is delivered with unbroken membranes, the placenta is most likely to be expelled in an intact condition. If the membranes have been broken, the embryo or fœtus usually escapes from the uterus, while the placenta and membranes remain within the uterus and are probably adherent to it. Suppose the embryo or fœtus has escaped; then, as is well known, the placenta and membranes will usually be expelled within twenty-four hours; yet in a large proportion of cases they will remain within the uterus for days, weeks or months. Does the continuance of the placenta within the uterus for even a few days at a non-viable period of pregnancy bring dangers to the patient? The answer to this must be absolutely in the affirmative. Such danger is a very considerable one to life, from both hemorrhage and septic infection. And even should the patient escape with her life, he does not believe that any ever escapes without serious injury to the childbearing

apparatus. Under such circumstances, arise conditions which are likely to produce sterility or to determine subsequent abortions. Such patients suffer, it may be throughout their sexually active lives, with disturbances of the functions of the vagina, uterus, tubes, ovaries, bladder and rectum, with varying degrees of other local and constitutional suffering.

Septic changes of the products of conception under such favorable conditions of warmth, moisture and contact of atmospheric air are developed so rapidly, that although absorption is probably not as rapid as at or near the full period of gestation, no one can say how soon the process of septic infection begins. The incipiency of such blood-poisoning is not heralded by any definite symptom. Even the rise of temperature, as shown by the thermometer, is not fully reliable unless observed every hour or two, and to wait until hemorrhage, or a rapid pulse, or a chill, or decidedly high temperature supervenes will prove in not a few instances to be waiting until a fatal result is inevitable. Or, should the uterus have emptied itself within a few days without evidence of danger of death, still in the great majority of such cases he believes that grave, and it may be permanent local damage will have resulted. We are told to let the placenta remain until there are evidences of danger, and then to remove it. Wherein is benefit to be derived from such a rule of practice? Is it not wiser to take due precautions against fire than passively to await the development of flames within the building? An abortion or miscarriage is a non-physiological accident; it is unnatural and pathological. There is no weight then in the argument that artificial removal of the placenta is unnatural and unphysiological, and hence should not be resorted to. Its retention brings to the woman her greatest danger, both as to life and to future usefulness. A uterus promptly and rightly emptied, uninjured by traumatism and rendered aseptic, becomes a source of comparatively little, if any, danger.

As in labor after the child has become viable, so in abortions or miscarriages, ergot is of great service after the uterus is empty. It then encourages involution, checks excessive lochial flow, expels clots and lessens septic absorption. Before the uterus is empty, this drug is seldom of more than limited value, and often is productive of actual harm.

When the hemorrhage is considerable and the ovum is intact, its administration will aid in controlling the loss of blood, but even here the tampon is usually sufficient. He believes that he has repeatedly seen the use of ergot retard the completion of the delivery by determining an undilatable condition of the cervix. Such belief has been strengthened by finding that under such circumstances the administration of an opiate hastens the delivery by relaxing a cervix that has been rendered rigid by ergot. In incomplete miscarriage there is nothing more uncertain than the action of ergot. After its use, the uterus may not empty itself for days or weeks, while the cervix closes so as not only to prevent the escape of the placenta, but also to prevent easy artificial extraction.

If you decide upon emptying the uterus, what is the best method of doing so? Prior to the third month, the small size of the cervical canal renders the introduction of the finger difficult, and the curette is here sufficiently efficient, either before or after the escape of the ovum. The thickened decidua may then be readily removed with this instrument.

After the third month, we have chiefly the placenta to deal with, and here the introduced finger is safer, more efficient and more reliable than any curette. The finger more thoroughly and more certainly removes all the products of conception, and tells the presence or absence of such complications as polypi, fibromata, etc. When reliance is placed solely on the curette, the uterus may be supposed empty when it is not; fragments of placenta and of membrane, or even the entire placenta may be left, with extreme risk to the patient.

If one is present at the time of the escape of the embryo, and the placenta remains, he should at once, while the os is dilated, introduce his finger into the uterus, and while depressing and steadying the uterus with the other hand over the abdominal wall, disect off *en masse* and completely the secundines and remove them. To effect this, it may be necessary to give an anæsthetic. After emptying the uterus, it should be at once syringed with a hot corrosive sublimate solution.

There will be, in all probability, no indication for a repetition of the intrauterine injection, though daily intravaginal antiseptic syringing for eight or ten days has been the author's practice. If the case is not seen until several hours have elapsed, and the placenta is still within the uterus, and ergot has not been administered, the os will be sufficiently dilatable to admit of an immediate resort to the prompt treatment. If, at that time, the cervix has already contracted because of ergot, the suspension of the ergot and the administration of an opiate, with non-interference of a few hours, will secure a dilatation of the os to such an extent as to permit the emptying of the uterus with the finger. If a number of days, or weeks, or months, have elapsed and the symptoms indicate an incomplete emptying of the uterus, and the cervical canal is closely contracted, it will be better to dilate either with laminaria tents or with graduated bougies, and to introduce the finger, than to rely upon any form of curette. After grave septic poisoning has occurred, a cervical canal that has been previously contracted undergoes a relaxation, and the placenta becomes detached or is so loosely adherent that its removal with the finger is usually a very simple procedure, and is, according to even the expectant practitioner, urgently demanded; but, immediately following removal of the placenta under such circumstances, evidences of more intense poisoning are frequently observed, and in many such cases a fatal termination eventuates.

There is but one form of curette that should ever be used for the removal of any of the products of conception. The perfectly dull wire curette is the only safe one. Every form of the sharp-edged instrument should be absolutely avoided. Simon's scoop is a dangerous instrument in the hands of the most careful. Much of the opposition to the curette is based upon the use of that or other cutting instrument. Even with the dull wire, due caution must be used not to injure the uterus. A softened womb may be penetrated by even a dull instrument. Dr. Parish's preference for the finger over the curette is based, however, rather upon the uncertainty as to the efficient working of the dull curette than upon its dangers. It would seem scarcely necessary to caution any one not to mistake the somewhat elevated and roughened placental site for portions of the placenta itself; but in one instance

he saw such a mistake made by an inexperienced gentleman who made active efforts with Simon's scoop until the uterine tissue was extensively gouged into by that dangerous instrument. Experienced men have left large masses of placenta—in fact, the fœtus and its placenta both—*in utero* after the cavity has been curetted. The possibility of double pregnancy with separate placentæ must not be lost sight of. He has seen an instance in which the physician removed with his finger, under anæsthesia, one fœtus with its secundines, and left within the uterus, unrecognized, a second fœtus and its placenta, until uterine contraction secured their expulsion.

Dr. Parish did not refer to the various complications of non-viable deliveries. They are numerous, and may call for special additional measures, but the management of the delivery rests upon no peculiar principle. Criminal abortion brings with it greater dangers, but usually the management does not differ materially from that of the non-criminal delivery. In the criminal variety septic infection may occur before the abortion or miscarriage has begun, and the expectant plan of treatment is attended with the greatest dangers. An injudicious introduction of the sound may engender a septic inflammation of the endometrium and determine a fatal result, before any part of the ovum is expelled. Under such circumstances, non-interference contributes to death.

In inevitable abortion he has repeatedly emptied the uterus by compressing the body between two or three fingers within the vagina and in front of the uterus, and the other hand over the abdomen. He has also secured, in a few instances, a prompt ending of an incomplete abortion or miscarriage by the injection of hot water into the uterine cavity, of course securing its ready outflow. The hot injection awakens active corporeal contractions with cervical relaxation, and, if the fluid is antiseptic, diminishes the danger of infection.

Dr. William Goodell took exception to but one point in this admirable study, and that was, to the use of the dull curette. He has given up the use of the dull curette, for several reasons. There is great danger of wounding the endometrium in its soft, thickened and vulnerable state. Then there is this very danger, the speaker had mentioned, of mistaking the placental site for tissue that should be removed, and the further danger, which he also admitted, of perforation. He was sure that he once penetrated the wall of the uterus with a sound, and without using any force—though, fortunately, he escaped an evil result. There is danger of wounding that portion of the uterine wall which is not at all implicated, if he might so express it; and especially, two or three days after the abortion, would this cause a liability to the creation of a fresh raw surface upon perfectly healthy tissue, with additional danger of infection. He uses two styles of forceps, one a small catch-forceps, which will seize anything that projects, or, still better, a small fenestrated polypus forceps, which can grasp any projecting mass, however small, and that only.

Dr. Regar asked how we can tell that the uterus is completely cleaned out? The finger cannot always determine with certainty. How long are we to keep up examinations and attempts at cleansing?

Dr. J. B. Walker thought that as long as the os is patulous the uterus contains something that needs removal: after removal contraction will occur. That has been his experience in several cases. He would ask Dr. Parish whether the rule holds good in all cases?

Dr. H. A. Slocum rather feared to follow the advice given to permit the ovum to escape entire. He remembered two cases which fortunately terminated favorably, but which gave him much anxiety, in which the escape of the ovum entire was followed by alarming hemorrhage. One of these was in a well-developed florid woman who had a history of repeated miscarriages. When he was summoned, she was bleeding slightly, and the labor pains were strong and constant. With his finger in the vagina he waited for the ovum to be expelled entire. It came with a gush of blood that blanched the ruddy face of the patient and left her pulseless. He was compelled to remove the pillows, elevate the foot of the bed, and with finger and hand endeavor to excite uterine contractions, after which, with hot water injections and other appropriate measures, the bleeding was controlled. When a uterus is distended with its contents, and the placenta leaves its site, and the large mass is suddenly expelled, it seemed to him that the sinuses will be left wide open, and the contractile vigor of the uterus will not suffice to close them.

He agreed with the advice to remove the placenta as soon as possible. He recalled a case, however, in the practice of a distinguished practitioner, in which, for what reason he did not know, it was left for six weeks free in the cavity, becoming hard and leathery, and was then removed under anæsthesia. His only connection with the case was to give ether, so that he knew nothing further of the circumstances than that the placenta remained for six weeks without giving rise to any bad symptoms.

Dr. W. E. Ashton took exception to the speaker's low estimate of the value of ergot. While it is contraindicated, except with a tampon, yet if the tampon be introduced and ergot then administered, the effect will be much more prompt and sure, and the presence of the tampon will prevent anything like hour-glass contraction. After a complete abortion he should consider intrauterine antiseptic irrigation uncalled for, and rather dangerous as tending to introduce air, and, therefore, germs, into a uterus which is otherwise in an aseptic condition.

Dr. Parish said, in reference to the use of the dull wire curette, Dr. Goodell could not have heard his remarks, or he must have failed to express himself clearly. He does not use it except at one stage, that is the third month; never after the placenta has been formed. He prefers the finger for many reasons, as he stated. Even with the dull instrument there is some risk of injury, and the method is unreliable. Dr. Goodell and he accord perfectly after the third month. Before the differentiation of the placenta, however, the smooth wire curette will detach and remove the deciduous membrane with no danger. He has used forceps, though not exactly the same form as spoken of, but the objection is that we cannot be sure with any form of instrument whatever that the uterus is empty. The finger alone tells us that. It is not only a therapeutic but a diagnostic appliance. It must be very rare for the uterus to possess the power to expel the ovum unaided and then fail to take care of itself. There must be some special morbid condition to which the hemorrhage is due. In the case narrated by Dr. Slocum, with its history of frequent miscarriages, he should have suspected a polypus.

He combines the use of ergot with the tampon, should the latter be insufficient when the ovum is intact to give a smooth mass on which to contract. Antiseptic injections are indicated after such a pathological process as a miscarriage. He doubted if the uterine cavity usually closes air-tight after such a process. Not infrequently there is a separation of the uterine from the fœtal layer of the placenta, with adhesion of the uterine portion. This adherent maternal layer is liable to give rise to septic inflammation and general infection. The patulous condition of the cervix is, to some extent, an evidence that the uterus is not empty, but the reverse does not hold good. It would be unsafe to conclude that everything had been expelled because the os is found to be contracted.

THE ONTARIO MEDICAL ASSOCIATION.

The Eighth Annual Meeting, held at Toronto, June 13 and 14, 1888.

(Specially reported for THE MEDICAL NEWS.)

(Concluded from page 25.)

THURSDAY, JUNE 14TH.

DR. A. HALFORD WALKER, of Hamilton, read a paper on the

TREATMENT OF NEURASTHENIA AND HYSTERIA BY REST.

After referring to the distinguishing characteristics of the two diseases, so frequently associated together, the author took up the question of the causes of the great increase of neurasthenia during the past few years, which he enumerated as follows:

1. Hereditary predisposition.

2. The school system of the present day, which he strongly and justly condemned, showing how utterly impossible it is for young girls to obtain sufficient recreation to enable them to become healthy wives and mothers, if they follow the curriculum and apply themselves sufficiently to their studies to keep abreast of their work.

3. Monotony of occupation. He strongly advised every one to have some pursuit outside of regular business, to cause a healthy reaction between body and mind.

4. The marriage of weakly people, which tends to produce offspring of the neurasthenic type.

He then considered the question of treatment, and showed by illustration what it is capable of doing after all other means have failed.

DR. BRAY, of Chatham, read a paper on

UTERINE HYDATIDS,

giving details of two cases, with expulsion of the contents of the uterus and recovery.

DR. MCPHEDRAN, of Toronto, showed a case of

SPLENIC LEUKÆMIA,

in which the spleen was very large. The patient was a clergyman, aged thirty-nine years, who enjoyed good health up to within three months ago, when the splenic enlargement was noticed. When first seen by Dr. McPhedran, one month ago, there was one white to thirteen red corpuscles, and the red were reduced to about sixty per cent. of normal, and they appeared deficient in coloring matter. Now the ratio was one to eight and one-third, but the red were decidedly of a deeper color, though reduced to only one-half the normal number. There were, besides, many hæmatoblasts. Notwithstanding this further depreciation in the character of the blood, the patient was feeling more bouyant and believed himself much better. The blood was demonstrated to the Association by a number of microscopes.

DR. HUSBAND, of Toronto, read a paper on

LIFE INSURANCE AND THE RELATION OF THE PROFESSION THERETO,

in which he set forth the duties of medical men in examining for insurance, that the work should not be done cursorily but conscientiously, as otherwise life insurance could not be successfully carried on. The general opinion of the Association seemed to be that the fee insurance companies allow is altogether inadequate to the duties to be performed.

DR. MCFARLANE, of Toronto, read a paper on

LAPAROTOMY FOR INTESTINAL OBSTRUCTION.

After pointing out the inefficiency of the methods of treatment pursued up to the present, he emphasized that laparotomy is the only rational course to adopt, and that it should be resorted to early and under the most careful antisepsis. The various steps of the operation were described, and the necessity for the greatest attention to all the minutiæ impressed upon all his hearers. The difficulties to be overcome were: (1) retaining the distended intestines in the abdominal cavity; (2) finding the seat of obstruction; and (3) deciding on the best method of dealing with it. Puncture of distended bowel was objected to as not safe; large, flat, warm sponges should be used to retain them in the abdomen. To locate the seat of obstruction, pass in the hand and examine all possible seats of hernial protrusions. Treves advises then to examine the cæcum; if not distended, the seat of obstruction will be above the colon. Then trace the small intestine up till the obstructed point is reached. If a part of the bowel is gangrenous, the question lies between making an artificial anus and exsecting a portion of the intestine. Of these two steps, the author was inclined strongly to advocate enterectomy in preference to an artificial anus. Illustrative cases were then cited. In conclusion, the writer urged the importance of early operation, as gangrene of the bowel has been known to occur within thirty-six hours after obstruction.

DR. YEOMANS, of Mount Forest, for diagnostic purposes, classified these cases as follows:

1. Mechanical, as volvulus, intussusception and hernia with strangulation.

2. Inflammatory, as peritonitis, enteritis, typhlitis.

Operative interference should be promptly resorted to in the first, and the expectant plan in the second.

DR. RICHARDSON, of Toronto, had no positive, but much negative evidence to offer in these cases. He had seen many cases die for want of operation, but he had seen no case relieved spontaneously. Hence, operation is to be recommended in all cases in which there is any probability of affording relief. He related a case in which obstruction had resulted from gas being forced through an ulcer in the mucous coat, causing separation of the mucous from the muscular coat, and thus pressing the mucous membrane to the opposite as completely to occlude the bowel.

Dr. Temple, of Toronto, read a paper on

THE RANGE AND USEFULNESS OF PESSARIES,

in which he said that with increased experience he resorted to pessaries less and less. Many cases which he formerly so treated he now relieved with tampons and suitable applications, not forgetting the general health of the patient.

PUERPERAL ECLAMPSIA, AND THE USE OF PILOCARPINE.

Dr. Irving reported a case of puerperal eclampsia treated first with morphine, potassium bromide, chloral, bleeding and croton oil. These measures failing, and a fatal issue seeming inevitable, one-third of a grain of pilocarpine was given hypodermatically. In about ten minutes, the dusky hue of the skin became changed to a natural color, and profuse perspiration, salivation and bronchorrhœa ensued. The convulsions, which had been very frequent for many hours, ended only two hours after action of drug began. Coma and stertorous breathing gradually gave way to peaceful slumber, and patient made a good recovery. Her urine had been laden with albumin. There was only slight pitting of ankles.

Dr. Olmsted, of Hamilton, then read a paper on

THE ANTISEPTIC TREATMENT OF INJURIES OF THE HAND.

He cited a number of cases to show the wonderful vitality of the hand and nature's ability to repair badly lacerated tissues, and by so doing making a protest against heroic surgery. He pointed out the advantages of moist dressings in badly lacerated wounds and the advantages of an early incision in palmar abscess, and the insertion of a short drainage tube in neglected cases. The whole hand should be enveloped in oakum which had previously been soaked in a solution of bichloride, a ring of oakum being placed around the drainage tube to prevent any obstruction to the outlet; wax paper or Mackintosh covering the whole.

THE REPORT OF THE COMMITTEE ON NOMINATIONS

was made as follows, and that the next place of meeting be Toronto.

President.—Dr. W. H. Henderson, of Kingston.

Vice-Presidents.—Dr. Geikie, of Toronto; Dr. Howitt, of Guelph; Dr. Day, of Trenton; and Dr. Aikman, of Collingwood.

Corresponding Secretaries.—Dr. Lovett, of Ayr; Dr. Gillies, of Teeswater; Dr. Trimble, of Queenston; and Dr. Leonard, of Napanee.

Treasurer.—Dr. N. Powell, of Toronto.

Secretary.—Dr. D. A. Gibbwishart, of Toronto.

The Association then adjourned.

CORRESPONDENCE.

THE OCTO-CENTENARY CEREMONIES AT BOLOGNA.

(*From an Occasional Correspondent*)

Bologna, when we arrived, was like an ant's nest stirred with a stick: flags, people, pretty women, students, soldiers—amusing and confusing. It was the day before the celebration began, and we had time to see the town in a night drive; the people were dim shades under the endless, arcaded streets; now and then a priest or two like darker shadows. The gray walls of the old city lacked nothing but the color of flags, court-dresses, soldiers and window-draperies to make the picture perfect.

On Tuesday, at 10 o'clock in the morning, we went to the great hall of the Syndic. The crowd at the door was dense, but we struggled in and wandered through vast museums and libraries with low bookcases, and over them the coats-of-arms of distinguished students. The servants were in black, with steel chains, silk stockings and pumps, and, in the crowd, soldiers and students in gowns of the red, yellow or black of various universities lent a color, amid a babel of tongues, all defiling into a great, arm-blazoned hall. On a platform stood Guerrachi and Capellini, Rector of the University, who presented us *en masse* to the Syndic.

At four, we put on our dress-coats to go see the King unveil Victor Emmanuel's statue. It was hot to slay as we went through the municipal palace to the Cathedral Plaza, where seats had been built in the big oblong square. Behind lies the civic palace, to the right the huge gray front of the unfinished Duomo, to the left the grand façade of the palace of Barbarossa's grandson, and in front a vast palace, now a bank. From every window hung red, yellow, blue and gold draperies, royal arms, gold on scarlet. In the middle of the seats was a dais with three velvet seats, and over it a crown and endless banners. Every one was in full dress, with chains, ribbons and decorations. When we were seated, the whole vast space filled with students in fancy dress and caps of many colors; next came soldiers and a dozen bands. Every window was full and 25,000 people in the plaza, with thousands of red, white and blue fans going, and at last the King and Queen and Prince came, and the band rolled out the Hymn of Italy, and a great roar arose "Viva el Re!" The statue was unveiled, some one made a speech and it was over.

Next morning early, we were all at the civic palace, and each delegation waited under its banner for tickets to be given out for the Syndic's dinner in the evening. The scene was curious. Universities from Melbourne to Harvard were represented by costumes past belief, gowns and hoods of all tints; all the French in yellow silk, one Hungarian in black with coral and gold buttons, gold lace, full cravat, etc.

Then we marched through the crowded and draped streets to the University.

The hall was a vast open court, two arcades high, filled above with men, women and uniforms, the pillars covered with lilies, roses and daisies—the Queen's flowers, the throne on one side, twenty feet from us, the bands all in the upper arcade, the students, with their old, battle-torn flags, in the outer circle below. The King, Queen and Prince came in and sat down, while the delegations in succession presented their addresses, one member speaking for all—Story for us; then we were presented to the royalties, shook hands with the Rector and fell back again, and so on from nine to two—the heat intense. In the evening, a good dinner at the Syndic's, round us a lot of Oxford Dons and Yankees—no speeches, and music low and gentle.

Next morning at nine, we met again in the covered court of the Archiginnasio—throne, flags, students, bands and gowns. The Deans of the Faculties read each a brief Latin exhortation, and then a list of the *laureati*, those

receiving the honorary degrees, Lowell in letters, some dozen in law, Agassiz in pure science, and in medicine Virchow, Liebermeister, Charcot, Spencer Wells, Weir Mitchell and others. The whole list was read first, and then the names called one at a time. As each went up, Dr. Guerrachi bowed, the Rector put on the finger of the *laureatus* a huge emerald seal, emblematic of marriage and fidelity to the University, then both greeted him, shaking hands. The Rector presented an illuminated diploma with a great seal, the recipient advanced, bowed to the King and Queen, who bowed in return, retired a few steps backward, and went down to his seat, amid the cheers which greeted all in turn. The Italian crowd cast fragrant bay leaves down upon the *laureati* as they went back through the streets.

A CANNABIS INOICA MIXTURE FOR PHTHISIS.

To the Editor of THE MEDICAL NEWS,

SIR: Dr. Bradshaw, in his article on "Some Points in Treatment at the Memorial Hospital, Orange, N. J." (THE MEDICAL NEWS, June 30, 1888), refers to a cannabis indica mixture I introduced into hospital use, and gives its formula. That was the one used several months ago. The mixture, as thus prepared, is very pungent and to some persons distasteful.

Messrs. Parsons & Co., of Orange, have, at my request, altered the original formula so as to make it read as follows:

Tr. cannabis indicæ . . .	f℥viij.
Ext. verbas. thap. fl.,	
Ext. verben. hastat. fl. (known as blue vervaine) . . .	āā f℥v f℥ij.
Syr. simp.	Oj.
Elix. aurant.,	
Tr. aromat.	āā f℥xij.
Mel. despumat.	f℥xxxij.
Spts. chloroformi	f℥iv.

Sig.—℥j to ℥ss p. r. n.

This is an elegant and palatable mixture, and affords great relief to many who use it. In some instances it increases the appetite, seldom impairs it; does not nauseate or constipate; hence, may be taken for long periods without harm.

Very truly yours, J. W. STICKLER.

EARLY MEMORY.

WE have received the following interesting note from a correspondent whose professional eminence is an unqualified endorsement of the accuracy of his observation:

To the Editor of THE MEDICAL NEWS.

I have recently seen in the medical journals that "Dugald Stewart was once asked what was the earliest thing he could remember. He said it was being left alone by his nurse in the cradle, and resolving to tell of her as soon as he could speak."

This may have been copied as a joke; but it brings to my mind the following statement that I have made from time to time for many years, which has always been received with derision, but which is a perfectly distinct remembrance in my mind: I remember being jolted over the crossings, in a baby-wagon, by a nurse, and resolving to tell of her as soon as I could speak.

June 9, 1888.

NEWS ITEMS.

The German Physicians of the late Emperor Frederick have published a statement concerning their participation in his case, an abstract of which has been cabled to the Associated Press and appeared in the daily papers. They state that in May, 1887, they pronounced the disease to be cancerous and recommended that the larynx be opened and the growth on the left vocal cord be excised —"a small operation which promised the best results." Of seven such operations which Von Bergmann had performed, all were successful. Sir Morell Mackenzie was then called in and opposed the operation and, the report states, gave his assurance that after a few weeks of treatment the patient would recover his voice and be able to command the autumn manœuvres. Dr. Gerhardt accuses Mackenzie of having removed for microscopical examination by Virchow pieces of tissue from the unaffected part of the throat.

Dr. Schroetter states that when he first examined the patient's throat in November, 1887, he decided that he was suffering from a cancer so far developed as to make it necessary to extirpate the larynx. Mackenzie, he says, then admitted that the growth looked like a cancer, but the Emperor Frederick refused the plan of extirpation because of the risks attending it. The German physicians thereupon signed a declaration placing the responsibility of the case upon Sir Morell Mackenzie.

Sir Morell Mackenzie is reported to have unqualifiedly denied the correctness of the above statement by the German physicians, and that in the course of a few days he might be able to publish a statement of the details as to the character and conduct of the case, from which, at present, he is precluded by State reasons.

International Congress of Dermatology.—Amongst those who have already accepted office in connection with the International Congress of Dermatology to be held in Paris in August, 1889, are: Dr. Ricord, Honorary President; Professor Hardy, President; MM. Emile Vidal, Ernest Besnier, Alfred Fournier, Hallopeau, Quinquaud, Tenneson, Henri Feulard, members of the Initiative Committee.

The South American Sanitary Congress. — *La Cronica Médica* of Peru publishes the articles agreed to at the American Sanitary Congress recently held at Lima, and signed by the delegates of Bolivia, Chili, Ecuador and Peru. The Congress had for its object the establishment of an international sanitary system amongst the South American States, with a view of checking the development and spread of infectious disease, especially cholera and yellow fever. Plague is also mentioned as a form of disease which is to be considered as coming under the regulations. The scheme provides for intelligence offices in each country, from which information as to the existence and progress of an epidemic shall be forwarded as promptly as possible—by telegraph in some cases—to the sanitary offices of the other South American States. A large number of minute instructions as to the use of disinfectants are drawn up, and a number of stringent rules relating to the admission of ships from ports where infectious disease exists to *pratique* are laid down. The time of quarantine in case of cholera is to be eight days,

and that in case of yellow fever ten days. Ports are in no case to be closed.—*Lancet*, June 30, 1888.

An Exhibition of Life-saving Fire Apparatus.—The strong public feeling aroused by the recent calamitous fire in Edgware Road as to the urgent necessity of all houses, especially large business premises where the higher rooms are occupied as sleeping apartments, being provided with ample and suitable appliances for securing the speedy escape of the inmates in case of fire, has led Dr. George Danford Thomas, coroner of Middlesex, to arrange for a display of life-saving apparatus and the various methods of preventing and extinguishing fires. This exhibition will be held at the Portman Rooms, Baker Street, W., at the end of July next, where the public will have an opportunity of being instructed in the use of fire-escape appliances and of testing their value.—*British Medical Journal*, June 30, 1888.

St. Joseph's Hospital, in Vienna, has received a donation of 50,000 florins (about $20,000) from Nathaniel v. Rothschild, for the erection and maintenance of an isolated ward for the care of children with infectious diseases.

Artificial Maturation of Wine by Electricity.—Signor F. Mengarini has published some results obtained by passing a powerful current of electricity, equal to nearly four milliampères, through various samples of Italian wine. Some acetic acid was found, and a perfume was imparted to the wine similar to that acquired by maturing. It is suggested that, if electricity can be made to destroy the mycoderma aceti so as to prevent the formation of acetic acid, it may prove a valuable method of treating wine. It is well known that it was at one time proposed to add salicylic acid to wines with this object. These are not the first experiments of the kind that have been made, as a short time ago Blaserno and Carpene examined the effect of the galvanic current on wine, and found that artificial maturation was thus induced, or, at all events stimulated, various oxidation products being formed.—*Lancet*, June 30, 1888.

Ladies' Kiosks in London.—The International Hygienic Society has done good work in a new direction, and the action it is now taking in supplying a much-felt, but unspoken, want of ladies in the shopping and promenading districts of the West-end, and of the working women in business thoroughfares, will certainly be one of the most important benefits that could be conferred upon these classes. The want has been a well-arranged place, where for a small sum a lady at a distance from home may retire to refresh herself with the necessary comforts of a lavatory, and where also she can rest for a little in quiet, write a letter and leave or receive parcels. The institution to be known as "The Ladies' Kiosk" will meet this want in a liberal and common-sense manner, and at a trifling charge. The Society named, proposes to place these kiosks in requisite quarters over London, and, having obtained two sites from the Duke of Westminster, has already nearly finished two buildings in two of the most frequented districts—in Grosvenor Street and Park Street.

The kiosk in Grosvenor Street is situated at the corner of that street and Avery Row, and is only forty yards distant from Bond Street. It is Italian in style, is faced with white bricks, and has stone dressings to the door. On entering, there is a small vestibule to be devoted to cut and other flowers—the former for sale—opening into a lobby with a marble dado and decorated walls. This lobby leads into a passage, from which open three apartments, with excellent sanitary arrangements and a communicating bell in each. The floor above has two more apartments, and close to, but quite separate from them a handsome lavatory, fitted up with two basins, with hot and cold water. There is also a dressing-table with general toilet requisites. The top floor contains a room for the attendant, who will live on the premises. On this floor is the water cisterns room. In the basement is the kitchen and living room of the attendant, and also a place with shelves for the storage of parcels. The attendant will be prepared to serve tea at a fixed tariff should it be called for. The building is heated in winter by hot water, and is lighted throughout with gas. The structure is highly ornamental, rounding off as it does the angle formed by the two streets, and thus obtaining a very prominent position. The kiosk in Park Street is similar in internal treatment, but is slightly larger, and has also the advantage of a writing room with appropriate furnishing. It stands close to the Marble Arch and Hyde Park. The cost of the two erections is stated to be £3000.—*Nursing Record*, June 28, 1888.

Dr. George v. Adelmann, Emeritus Professor of Surgery and Ophthalmology at the University of Dorpat, died at Berlin, on June 16th, aged seventy-seven years. He was graduated at Marburg, in 1835, and became an assistant at the medical clinic of Heusinger. In 1837, he was made an assistant at the surgical clinic of Ullman. In 1841, he was called to the chair of Surgery at Dorpat, made vacant by the departure of Pirogoff for St. Petersburg, which position he held for thirty years, until 1871, when he was made Emeritus Professor. He then removed to Berlin, taking a lively interest in scientific questions. He was a frequent contributor to medical literature. He presided at the last meeting of the Union of Berlin Surgeons, on June 4th.

The funeral ceremonies were held on June 19th, in the chapel of the Surgical Clinic of the University. A eulogy was pronounced by his former pupil and son-in-law, Prof. v. Bergmann.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 3 TO JULY 9, 1888.

Bentley, Edwin, *Major and Surgeon.*—Retired from active service, July 3, 1888, by operation of law.—*S. O. 153, A. G. O.*, July 3, 1888.

Crosby, William D., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended one month.—Par. 8, *S. O. 151, A. G. O.*, June 30, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JULY 7, 1888.

Crandall, R. P., *Assistant Surgeon.*—Detached from the U. S. S. "Saratoga," and ordered to the U. S. S. "Galena."

Peck, George, *Medical Director.*—Placed on the retired list, on the 9th instant.

ORIGINAL LECTURES.

THE CEREBRAL PALSIES OF CHILDREN.

Clinical Lectures delivered at the Infirmary for Nervous Diseases.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, PHYSICIAN TO THE PHILADELPHIA AND UNIVERSITY HOSPITALS AND TO THE INFIRMARY FOR NERVOUS DISEASES.

LECTURE II.

INFANTILE HEMIPLEGIA (*Concluded*).

SYMPTOMS.—Complex and varied as are the symptoms of infantile hemiplegia, they fall naturally into three divisions: those of the onset, those pertaining to the paralysis, and the sequences; and in this order we shall consider them. The period of *onset* is usually characterized by convulsions and coma, indicating serious disturbance of the brain functions; but there are exceptions to the rule. Thus, in three cases the disease came on *suddenly*, in apparently healthy children, without spasms or loss of consciousness.

Case IX.—Nellie M., æt. twelve years. H., 280. Came on when one year of age, suddenly, with pains; no spasms; whole left side affected; gait hemiplegic; arm and leg swollen and shorter than fellows. Right calf eleven and a half inches, left eleven; biceps, right eight, left seven and three-quarters; dynamometer, right sixty-five, left thirty-five; left side is cold.

Case XXXVIII.—William M., æt. four years and six months. I. P.$_4$. 84. Good family history; was well until three years ago. While playing he became suddenly powerless on right side; had no convulsions, but was comatose for a time; no fever. The face was included and the loss of power was complete. Is a delicate child. Some mental deterioration. Had convulsions ten days before application and now cannot walk.

In Case LXXVII., the hemiplegia came on while the child was dressing one Sunday morning, after an indisposition of a few days' duration.

A *latent*, gradual onset is more common and was noted in ten cases.

Case III.—Joseph D., æt. two and a quarter years. H., 219. When six months old the mother noticed loss of power on the right side. This condition persists; the hand is closed, and there is talipes varus of the foot.

Case VII.—Daniel McS., æt. four years. H., 253. Natural labor. When one year old it was noticed that he could not sit up and seemed weaker than natural. Has begun to walk within the past few weeks. Has right hemiplegia with contraction of flexors; walks very badly; does not talk, but understands what is said to him.

Case LXXI.—Alphonse N., æt. fourteen years. H., 299. Is one of eight children, five of whom died in infancy. Walked at two years and then walking gradually became impaired. There was no sudden attack. *Status præsens:* Right arm and leg wasted; the right shoulder-joint and blade project, and the whole side looks smaller. The hand is cold and there is marked mottling of skin of legs and arms; choreic movements of right arm, and at times an irregular, jerky motion of the right leg; reflexes present; superficial exaggerated on affected side; heart normal.

Case LIII.—Frank H., æt. fourteen months. I.P.$_4$. 169. Healthy and strong when born. When five months old, while teething, went into a fit, at first very severe, almost every hour for a week, then once or twice a week. Has them now on Mondays, in the afternoon. Noticed feebleness of left side of body; does not know exactly when first observed. There is loss of power on the left side; with contracture of the left arm and hand, with shortening and contractures in left leg. Cannot walk or even stand alone. Improved, particularly the arm, under treatment.

Case LII.—Henry I., æt. five years. I.P. b., 37. Parents healthy; healthy at birth; never has used left hand. At eight months observed that thumb was drawn across the hand, fist closed; this became worse. Began to walk at two years, then noticed that left leg was weak. Had a fit at eight or ten months, another a year later, none since. Mind not good. Grip good; contraction in biceps, supinator longus and muscles of hand; hand flexed at right angle, can be easily made straight. Arm much smaller than right.

Convulsions. In the majority of the cases the disease began with convulsions, partial or general. In fifty-two of the ninety-seven cases on our records, this history was given, which corresponds very closely with the figures of Wallenberg: forty-three of eighty-eight cases in which the history was definite; thirty of the eighty cases collected by Gaudard, and in "more than half" of the eighty cases of Gowers.[1]

The following set of cases will illustrate the prominence which this symptom deserves in the clinical history of infantile hemiplegia.

Case X.—Reta O'N., æt. two years and four months. H., 285. When fifteen months old, in April, during teething, had a convulsion; perfectly well before the attack, which came on suddenly and was confined to the left side and lasted eight hours. In July she had a second attack, the convulsions lasting twenty hours. After the April attack there was complete paralysis of left arm, leg and part of face; no strabismus. The second attack did not increase the paralysis. She had begun to recover power before the July convulsions. Reflexes increased on affected side.

[1] Gowers: A Manual of the Diseases of the Nervous System London, 1888. Vol. ii.

Case XX.—Francis H., æt. five years. I.P.$_1$, 81. Two older children. Healthy child until eighth month, when teething. It then had convulsions, four in number, very violent, which were followed by left hemiplegia. The fits have continued ever since at intervals of a few weeks. Has never walked; intellect feeble; left arm and hand contracted and stiff, but the stiffness can be overcome; the forearm is shorter; stands on the inside of right foot.

Case XIX.—Ella H., æt. four years. H., 309. Was well until her second summer. One night had a convulsion, and in the morning was found to be paralyzed on the left side. Gradually recovered, and can now walk well, though stiffly, and the leg assumes various positions while at rest; attempted movements of the arm will bring on associated movements of the leg and foot. In walking the arm is carried stiffly, extended and pointed backward. Voluntary movements of the hand are slow and performed with difficulty; the fingers do not grasp well; reflexes are a little increased on left side.

Case XX.—Nellie P., æt. five years. H., 316. One of three children; eldest child had spasms; parents healthy; was natural when born. Convulsions when one year old, while teething; they were confined to the right side and lasted from 8 A.M. to 5 P.M. After this the side was paralyzed. Has had no spasms since. Uses arm awkwardly with some incoördination. The right hand and arm are smaller than left; walks with an apparatus.

Case XXVII.—Lewis P., æt. sixteen years. I.P.$_1$, 209. Born healthy. At the age of three months was seized with spasms. There is a doubt whether or not they were confined to the right side. This was followed by partial loss of power on right side. Has never used arm and leg well since, and they are now shorter and in a state of rigidity. The leg is dragged and the gait is hemiplegic; arm and hand very rigid; intellect somewhat impaired.

Case XXIX.—Elizabeth W., æt. seventeen years. I. P.b., 142. Family healthy; child was healthy when born, and well up to twelfth month. Had a slight fit and lay insensible all night. Was thought to have water on the brain and was leeched. Was ill four weeks. Paralysis then came on, involving left side except the face. Leg rapidly recovered power and she walked in a month. The left arm and leg shorter than the right, and the muscles are stiff. Has power of movement in the arm, and the fingers are flexed, and she does not use them. The left arm is two and one-quarter inches shorter than the right, and the left leg one and one-quarter inches shorter than the right. No difficulty in speech. Intellect impaired.

Case XXXII.—Joseph McC., æt. two years. I. P.$_4$, 28. Mother very nervous. Attack came on November 7, 1882, when the child was about a year old. He had vomiting and purging, convulsions and coma, after which the paralysis affected the left side; came on suddenly. Face not involved. The paralysis has not improved much. Reflexes increased on left side.

Case XXXV.—Agnes H., æt. six years. I. P.$_4$, 55. Healthy as a baby; dentition slow. When sixteen months old had convulsions, fever, and sudden paralysis of right side of the body, involving the face. Gradual return of power in face; gait hemiplegic.

Case XLII.—Joseph H., æt. eighteen months. I. P. 3, 189. Natural labor. Child healthy when born. In October was taken suddenly with high fever; no convulsions. The fever subsided in a week. He continued very irritable and nervous for a month. Week before Christmas had convulsions, lasting for fourteen hours, and he was paralyzed in the left arm and leg. The following day unilateral spasm began and continued until evening. He has never had any more spasms. The palsy continues, with, of late, improvement in the leg. *Present state:* Weakness and partial palsy of whole of left side with considerable rigidity of flexors of fingers: no deviation of face now, though there was some at first. Died of the unilateral convulsions just eleven months after onset of the disease.

Case XLIV.—Mary M., æt. nineteen months. I. P. 3, 165. One other child has had spasms. In July had "spasms." Woke from sleep in them; the left side was convulsed and, after spasm, found to be palsied. Two days later had eighteen attacks; after this left arm and leg seemed a little better. Face was drawn to left side. After a few days ceased having these violent spasms. Began to walk in two months. Since then she has had momentary attacks of unconsciousness, occurring at first daily, now every two or three days. *Present state:* Healthy looking; no atrophy of muscles; no contractions. Left arm and leg weaker than right. Falls easily. Face not drawn.

Case XLIX.—Mary M., æt. fourteen months. I. P. 3, 337. Youngest of three children. Well until July 6th, when she had spasms all afternoon and evening. No fever or diarrhœa. Said to have had congestion of lungs. Face, arm and leg on right side palsied. Began to move right leg at end of week. Arm still palsied.

Case L.—Jennie A., æt. fourteen years and ten months. H. 1, 348. Was healthy when born. Labor natural. Enjoyed good health until about a year old, when she had convulsions, suddenly followed by coma, which lasted several days, and, on recovery, she was noticed to have lost power on the left side of face, arm and leg. For several months the palsy persisted, but she gradually regained the use of leg and then of the arm, but the face has never changed; for this she now comes to the hospital. *Status præsens:* A fairly well grown girl, rather nervous and timid, and the father says she worries herself and has fits of despondency. There is complete paralysis of the lower facial muscles on left side; mouth is drawn to the right. Can shut the eye, wrinkle, and elevate the brows, but there is no movement of the lips on left side, nor does the ala expand. Face on this side a little smaller. No loss of sensation. Arm is used quite well; no weakness of hand. Dynamometer: R. 75; L. 65. Can run well; no difference in the legs. Reflexes normal. On watching the face it is noticed that, from time to time, there are choreiform twitchings in the muscles of the face on the left side; most marked when the muscles of the normal side are in action. Quantitative, but no serial changes in electrical reaction of the paralyzed muscles.

Case LIV.—Thomas McR., æt. ten years. Well until eight months old, when he had spasm of the left hand, and the whole left side seemed weak. No statement as to general convulsion. When two years old had seven convulsions, and has had eight since then. Fever often precedes the attacks. There is contracture of the left arm, and the hand is weak, though the fingers can be moved. There are, at times, slight spasmodic movements in pronation. Left leg drawn up by contraction of gastrocnemius.

Case LV.—Joseph D., æt. eleven years. I. P.a., 107. Healthy when born. When three months old had convulsions, after which it was noticed that he did not use the right hand. Had twitchings and spasms as an infant, and, at three years, a severe convulsion lasting from 10 A. M. to 10 P. M. Has not had violent spasms since. Walked when two years old. *Status præsens.* Walks badly on account of contraction of right gastrocnemius. Movements of right arm limited. Cannot extend the wrist; fingers flexed. Grip fairly good.

Case LVI.—Harry S., æt. three years. I. P.a., 159. Well until the tenth month, when, during an attack of catarrh, he had a severe convulsion lasting seven hours, chiefly on right side, and for three days lay in a stupid, semi-comatose condition. Could not use the right arm after it, and the right leg was weakened. The mouth was drawn to the left side, but became straight again. When a year old had a second convulsion while teething. Gait hemiplegic; cannot lift the toes; right leg well nourished. Contraction and spastic condition of the right arm.

Case LIX.—Mary H., æt. six years. C. D. C., 80. Parents healthy; one brother had convulsions while cutting teeth. Healthy until third year. Fit came on while in perfect health. Fit began on left side, then became general; lasted nine hours. Insensible for some hours. Could not see for two days. Left side completely paralyzed. Could not move left side for three months; improvement beginning in hand. At end of year could walk. In September had fits again, but was not more paralyzed. Fits again in March. Three attacks of fits since. Last attack, one year ago, completely palsied the left side again. Ever since first attack mind affected; bad temper; bites. No atrophy of left arm, no contracture; left arm seems weak; walks and runs. Has fits now.

Case XXX.—Christian A., æt. eight years. I. P.a., 19. Healthy when born. When six months old had very violent fits. When three years of age had one day convulsions from 4 A.M. to 7 P.M. Had summer complaint badly during the first eighteen months of life. After the first fit lost power on the right side of the body and in the limbs. Chorea gradually developed. *Status præsens:* Is well grown and intelligent; goes to school. The right arm and hand are weak, and he can flex and extend the fingers, but when he attempts to perform any volitional act, irregular movements come on and prevent their successful performance. The grasp of the right hand is decidedly weaker than that of the left. When at rest the right hand is closed and the thumb flexed across the palm. The right leg is colder than the left and the heel is drawn up by contraction of the gastrocnemius. The foot is inverted, pes equinovarus. There are no choreic movements in the leg. The tendo Achillis was cut and an apparatus applied which relieved him very much and enabled him to walk much better.

Case LXIX.—Henry L., æt. fourteen years. When eighteen months old had general convulsions which lasted ten days, and left the right side paralyzed. Gradually recovered the use of the leg, but the right arm is atrophied and weak, and displays constant choreic movements. No contractions. Walks quite well; general health good.

Case LXXVIII.—Amanda C., æt. thirteen months. I. P. 3, 375. Born without instruments. In October, when seven months old, had spasms and was unconscious from Saturday to Wednesday. Spasms began in left arm and right leg. On Wednesday the arm and leg were noticed to be palsied. *Status præsens:* Is unable to sit alone; falls toward the left side. Rigidity and contractures of left arm and leg, with marked choreic movements. Muscles not wasted. The thumb is turned into hand.

Loss of consciousness almost invariably accompanies the convulsions, and may last from a few hours to many days. In a few instances coma occurred without convulsions.

Case IV.—Lizzie E., æt. twenty-one months. H., 237. One of two children. Was healthy when born and until sixteen weeks ago, when, in the evening at 10 o'clock, had a most intense headache. She had seemed to have frontal headache for about two months. She became unconscious and did not revive until 11 o'clock. She attempted to rise but fell to one side. She was able to walk upstairs and nothing wrong was noticed in the limbs. The next morning the child could not move the right arm or leg, and had lost completely the power of speech. Three days after could move the leg, and walked again in three weeks; regained speech on third day. Has for the past seven weeks begun to use the arm. Patellar reflex is increased on the affected side.

Case XLVIII.—Bertram T. B., æt. five years, I P. 3, 279. Family history good. Elder of two children. Two years ago, in July, had an attack of left hemiplegia. Unconscious for six weeks; no convulsions. At end of six weeks began to move right arm and leg. Two months later began to move left leg. Has not improved much since. Considerable wasting on left side, and the foot is somewhat smaller than right foot.

Fever. The records are not complete on this point, and it is not often mentioned whether or not the temperature was elevated. Fever may be transient or persist for weeks as the following cases illustrate:

Case XLV.—Lewis S., æt. two years. I. P. 3, 11. Youngest of six children; others healthy. Parents healthy. Well until September. While playing on floor, fell over, and on examination it was found that he did not use left arm and leg well. Paralysis of leg soon became complete and of arm incomplete. Began to use arm in one week, and, in a month, could sit alone and draw up leg. On day of attack had fever, was restless, did not vomit. No retraction of head and no bladder trouble. Fever disappeared in a day or two; soreness to touch remained for two weeks. *Status præsens:* Has improved very little in leg. Is a well-nourished looking child; left leg atrophied. No difference in length of legs, but left foot one-quarter inch shorter. Can flex and extend leg and thigh; extends foot, but cannot flex it. Flexes and extends toes. Talipes equinus; sensation normal.

Case XLI.—Jennie E., æt. four years. I. P. 3, 195. In April, had fever and delirium lasting almost four weeks. At about end of fourth week the mother noticed that right arm and leg were paralyzed. Speech was also a little affected. *Status præsens:* Right leg a little shorter, about one-quarter of an inch; and foot also. Slight atrophy of leg. Has all movements of leg and arm. Arm slightly atrophied; no change of temperature. In walking she limps, and there is slight "genu recurvatum." There are slight

involuntary movements of affected limbs, noticed when excited. September 24, 1879, movements have ceased; walks better, some rigidity of right arm.

Strümpell, Gaudard, and others mention fever as an invariable accompaniment of the convulsions which usher in the disease in such a large proportion of the cases.

Delirium, which is noted by some writers as preceding or replacing the convulsions, was observed in Cases XLI. and LXXXIV.

Vomiting is especially mentioned in only four cases.

Soreness of the general surface was observed in Cases XLV. and LXIV.

Screaming spells preceded the attack in one case.

Doubtless many children die in the convulsions or in the subsequent coma, without reaching the second or paralytic stage of the disease.

The hemiplegia, which is noticed as soon as the child recovers consciousness, is usually complete. Less frequently there is, at first, paresis which gradually results in complete loss of power, and in some instances the total paralysis was only established after repeated convulsions, as in Cases LIX. and LXXXV. In sixty-eight cases the right side was involved, in fifty-two cases the left.

The *face* is not always affected; the exact proportion is uncertain as the point was not constantly mentioned. As is the rule in facial paralysis of cerebral origin, the superior muscles are not involved, and the child can close the eyes and elevate the brows. Rapid and complete disappearance of the facial palsy is the rule, and, of the cases which returned for examination, in only one did the condition persist, and in this, strange to say, no trace remained of the paralysis of arm and leg. The child, aged fourteen and one-half years at time of observation, had been completely hemiplegic at the age of one year; the arm and legs had gradually improved, but the face was drawn to the right and there were choreiform movements in the paralyzed muscles of the left side. The tongue did not seem to be affected, but the uvula deviated strongly to the right. Dr. Sinkler has at present in the wards a girl aged thirteen, who became hemiplegic in infancy, and has still complete facial palsy; and in Case XCVI., the last of the forceps cases, there were paresis and atrophy of the facial muscles.

As with the hemiplegia of adults, the residual paralysis is most marked in the arm, which displays more or less wasting, and is, as a rule, useless for the ordinary purposes of life. There may be arrest of development, leaving a wasted and withered member; more commonly, there is only a moderate degree of atrophy. In extreme cases the arm is held close to the side, the forearm strongly flexed at right angles and in the semi-prone position; the hand flexed and the fingers contracted in the palm, usually embracing the thumb. Motion may be almost lost in the arm and completely lost in the fingers. In a majority of the cases there is considerable power of movement, and the arm can be lifted above the head and flexion and extension made at elbow and wrist. The finer and more delicate movements of the hand are rarely recovered, and, while many of the cases possess a useful limb for carrying or grasping purposes, actions requiring manipulation with the fingers cannot be effected. The grasping power is often remarkably good. The leg, as a rule, recovers more rapidly and more completely than the arm, and the palsy may completely disappear, an event which very rarely happens in the upper extremity. The wasting is never so marked, nor does arrest of development often occur. In only one case, VI. of the Elwyn series, is the leg much atrophied. But even when of fair size, and of good muscular development, there is evidence of impaired power in the persistent halt which is such a characteristic legacy of hemiplegia. The patient may simply "favor" the affected side, noticeable, perhaps, only on rapid walking. A very perceptible dragging of the limb is more common. There may be tremor of the leg while in motion.

Rigidity was present in a large proportion of the cases at the time they came under observation. So marked is this feature of spasm that the disease has been termed spastic infantile hemiplegia. Although a very frequent, it is not a constant symptom, and there are cases in which the paralyzed limbs are quite relaxed, even years after the onset of the affection. In Cases IV., V. and VII. of the Elwyn series the arm is flaccid; and in Case X. the spasm is very slight. The rigidity disappears during sleep; it is increased by emotion and aggravated by any attempt forcibly to overcome the spasm. When the rigidity is extreme and has lasted for years, permanent contracture may result, in which condition relaxation is no longer possible, on account of the structural changes which take place in the muscle.

The *reflexes* are almost invariably increased in the affected limbs. The knee-jerk is exaggerated, and, in many cases, the ankle clonus can be obtained. As often happens in hemiplegia, the reflexes may be heightened on the sound side. A rectus clonus can sometimes be got, and, in several of the cases, making sudden tension of the spastic fingers developed a clonus on the flexors. In three cases the reflexes were absent—Cases I. and VIII. of the Elwyn series, and IX. of the Infirmary patients. In the Elwyn cases there is rigidity, which in the other is very slight. They are not necessarily absent in the instances of flaccid paralysis.

Sensation is not often disturbed; it has been normal in all the cases which I have examined, and it is not once mentioned in the records as absent.

Vaso-motor disturbances, such as coldness of the affected extremities, blueness and congestion, are not uncommon, particularly when the paralysis is extreme.

The *electrical reactions* are usually normal; occasionally quantitative, but never qualitative changes are noted. None of the recent cases examined in the electrical department, by Dr. Willets, have shown alteration of other than a slight diminution.

Post-hemiplegic movements. It was from this hospital, and based chiefly upon a study of cases of infantile hemiplegia, that Dr. Weir Mitchell first described those disorders of movement which are known as post-hemiplegic chorea, mobile spasm, athetosis, hemi-ataxia and post-hemiplegic tremor. There were thirty-one cases in the entire series which presented these movements. Three varieties were noted:

1. *Post-hemiplegic tremor*, which was present in only one case (LXXXV.), and occurred in the entire arm, chiefly when at rest.

2. *Post-hemiplegic chorea*, or, more correctly, hemi-ataxia. The great majority of the cases, twenty-four in number, come in this division. The movements were in-

coördinate and choreiform, chiefly noted on voluntary effort. Many instances of this have been described in the report of the cases.

3. *Mobile spasm and athetosis*, noted in six cases.

The following are good illustrative cases:

Case XCI.—Mary H., æt. eleven years. I. P. I., 161. When two years old, had "a spell of sickness" which lasted some time, and in which paralysis of the left side gradually came on. She did not walk until the fourth year. . . . She now favors the left side in walking, and the arm and leg are stiff. Has slight power over arm, but it and the hand are in constant, irregular motion; fingers are extended in regular order, and she has no control over them. She can move the arm about quite well.

Case LXXVI.—Edith W., æt. six years. H., 301. Birth natural at full term. Father died of phthisis. At four or five months noticed that the child did not use the right arm. Began at two years to pull herself up by a chair, and at two and a half years learned to walk, and then dragged the foot. Has been improving. Face not affected. Is intelligent. Choreic movements of right hand and arm. January 25, 1888, condition as follows: Is a well-grown, fat child. Walks with a decidedly hemiplegic gait. Sits with hands quiet in her lap, the right on the left. When excited, or on attempting to make any movement, there are irregular choreic movements in the right hand and arm. In grasping an object picks it up with the hand, not with the fingers; as the object is approached the fingers jerk in various directions, are separated from each other and extended in more or less orderly sequence. Some stiffness in the arm during these movements. Very similar motions are present in the foot and toes, and the leg is a little stiff. Knee-jerk in right leg exaggerated; no ankle clonus. Intelligence good.

In one case there were associated movements of the paralyzed arm on attempting motion with the other one. Allied to this, doubtless, is the not infrequent irregular jerking of the arm in the act of walking. Sometimes it is thrown in a curious way behind the back.

Aphasia. Speech was affected in thirteen cases, in five of which the children were under three years of age.

The following are illustrative cases:

Case I.—Cecilia P., æt. twelve years. H., 25. Healthy when born; one of seven; others healthy. Father has had hemiplegia for three months. When two years old awoke paralyzed on right side; became comatose and remained unconscious for two days. Lost power of speech for six weeks. Paralysis persisted for six months; the leg gradually improved. Rigidity came on in affected side a few months after the attack. Has had, at times during the past three years, loss of consciousness, with convulsive movements chiefly of right side. Has had two or three in a day but may not have any for a week or more. Has a characteristic hemiplegic gait. Leg is a little stiff; muscles somewhat wasted; one arm smaller than the other and flexed; the fingers also flexed and contracted.

Case XI.—Robert M., æt. thirteen years. H., 91. No injury at birth. One year ago sudden paralysis of the right side, which was preceded for a day by loss of power of speech. The face was also drawn. Had convulsions a few weeks after the hemiplegia, but not at the time. Began to walk eight weeks after the attack, and recovered speech about the same time. Arm has improved but little; is stiff. Convulsions at intervals. Is improving.

Case XXVIII.—Mathew C., æt. ten years. I. P.$_4$, 19. Good family history. Well until August, 1883, when present trouble began. Had vomiting, diarrhœa, great headache and photophobia, which lasted four days, and on the fourth day there was complete, right hemiplegia, including face, with aphasia. In a month the child began to get about; the aphasia was complete for one week, and then the power to walk gradually returned. Walks well but slowly and stiffly. Arm contracted. Right face is still smooth, and the dimple is gone.

Case LVIII.—Ellen McC., æt. six years. C. D. C., 177. Parents healthy. Healthy until three years of age. Then had a fit, lasting, with intervals, for nine days, and, at the end of that time, convulsive movements confined to right side; right hemiplegia followed, and also loss of speech. Gradually regained power of walking; has not yet regained power in arm. Began to speak in a year, and mental condition improved. Ever since first attack has had attacks of unconsciousness every day; jumps, falls to ground and immediately rises again, looking bewildered. No prolonged convulsion until ten days ago. During this time has had none of the lesser attacks. Has had as many as fifty to sixty of these "jumps." Injures herself much by the falls. During attacks, convulsive movements of left side of body and face, and she screams. Does not bite tongue; speech affected since second attack. *Status præsens*: Right arm smaller than left; contractions of flexors of forearm and wrist, not of her fingers. Right leg trifle shorter than left, and slight contraction of tendo Achillis.

Of these thirteen cases twelve were associated with right and one with left hemiplegia. The number affected is much smaller than in the collected series of Wallenberg,[1] whose statistics give forty-five cases of speech disturbance in ninety-four right hemiplegias and seventeen cases in sixty-six left hemiplegias. In Gaudard's[2] fifty-five right hemiplegias there were twenty-five cases of disturbance of speech, seventeen of which were true aphasia. There were eight left hemiplegias with aphasia. Bernhardt,[3] who has made a very careful study of this condition in children, says that in a majority of the cases of cerebral palsy, no matter on what side, there is affection of speech, usually transitory. In one case of our series the aphasia was associated with left hemiplegia. Usually the power of speech begins to return in a short time, but recovery may be deferred for a year (Case LVIII.) and in Case XVII., the child had not spoken six months after the lesion. In several instances recovery was incomplete.

In eight of the twenty-two cases at Elwyn, there is absence or profound disturbance of speech, but the patients are idiots or idio-imbeciles who have never acquired fully the power of speech.

Mental defects. A lesion so serious and extensive as that which is associated with infantile hemiplegia may seriously interfere with cerebral development, and, among the most common sequences, we find various anomalies of intelligence. In the Infirmary series only twelve cases presented idiocy or imbecility at the time of observation, but it must be remembered that the majority of the cases came to the Infirmary a short time

[1] Loc. cit.
[2] Loc. cit.
[3] Virchow's Archiv, Bd. 102.

after the onset of the paralysis, so that our records on this special point are by no means complete. In Gaudard's series—80 cases—there were 15 feeble-minded and 19 idiotic children, while in Wallenberg's cases (160) there were 50 with mental defects, and in 15 cases imbecility followed the epilepsy so often associated with this condition. Three grades may be distinguished: idiocy, which is most common when the hemiplegia has existed from birth, or has come on at an early period; imbecility, which may increase with the development and persistence of convulsions; and a feeble-minded, backward condition, a retarded rather than arrested mental development. The 23 patients at the Pennsylvania Institution for Feeble-minded Children may be classified as follows: Idiots, 4; idio-imbeciles, 2; low grade imbeciles, 5; middle grade imbeciles, 6; high grade imbeciles, 6.

In connection with the mental disturbance which so often follows infantile hemiplegia, Merklin[1] has called attention to the development, later in life, of psychoses, even in cases which, in youth, have not shown any abnormalities.

Epilepsy. One of the most common and distressing symptoms is the occurrence of convulsive seizures, usually confined to the paralyzed side, but tending to become general. This hemiplegic or post-hemiplegic epilepsy affects, sooner or later, a considerable proportion of the cases. In the Infirmary series of 97 cases there were only 20 instances. In Gaudard's list (80) there were 11 cases of hemi-epilepsy, and 66 in Wallenberg's series of 160 cases. At Elwyn of 23 cases, 15 had epilepsy.

The attacks begin a variable time after the onset of the hemiplegia, mostly within two or three years, though they may be deferred eight or ten years, or even longer. In some instances the paralyzed limbs are convulsed within a few weeks.

These seizures may be either (1) attacks in which the child is simply dazed for a moment or two, occasionally longer, without any motor involvement; (2) spasms beginning in and confined to the affected side, without loss of consciousness—the true Jacksonian epilepsy; (3) general convulsions which begin in the paralyzed limbs, and are usually accompanied by loss of consciousness. All three forms may occur in one case, but by far the most common and characteristic is the hemi-epilepsy with retention of consciousness.

The following illustrative cases will give an idea of these attacks:

Case XCVI.—Patient of Dr. Mitchell, at present in the house. The hemiplegia is left-sided, and dates from shortly after birth. As the child sits on the floor the eyes will suddenly become fixed, deviate strongly to the left, the head begins to nod (the so-called nodding epilepsy, E. nutans). The left arm, which is constantly stiff, may be more closely retracted, but often the fixing of the eyes and nodding motion of the head alone indicate that a fit is present. After a few moments the child wakes up with a start and resumes its play.

In *Case LXII.* the child, æt. two years, became hemiplegic (left) at the tenth month. When twenty months old she began to have spasmodic contractions of the left arm and leg, lasting for about five minutes, and occurring several times a day. The arm would be jerked up, the leg twitched, and the eyes became fixed. Just before they come on, she gets quiet, and, if nursing, drops the nipple. With cessation of the attack she draws a deep breath, and is then as bright as ever.

In the following case the lad had post-hemiplegic movements, as well as distinct convulsions, which sometimes become general:

Case LXVII.—Charles W., æt. thirteen years. H., 323. Was healthy as a baby. Birth natural. In August, 1881, had a "sick spell" from Wednesday to Friday. While dressing on Sunday, lost power entirely in left arm, leg and face. Was in bed two months. He slowly regained power of leg. Since then has had fits. *Status præsens:* Is fairly intelligent; has bent head; no scar on head. Characteristic hemiplegic gait; drags the left leg; left arm smaller than the right; it is wasted, and possesses very slight power of movement—chiefly flexion. Spastic rigidity of flexors of the wrist, so that the carpus cannot be extended. Often in the day, as many as ten or fifteen times, the arms will stretch out from the side, and the fingers will extend, first the little and then the others in order. Face muscles will also work. He has other sorts of attacks, in which the movements may begin as these, and be confined to the arm or extend to the entire side of the body. He never loses consciousness, and never sleeps after the attacks. Has as many as three or four in a day. He has headache, but not worse on one side. Knee-jerk exaggerated on left side.

Case XVIII.—Annie E., æt. ten years and six months, I. $P._1$, 157. Three other children. Was quite healthy until the sixth year, and was a very bright, intelligent child. Had a convulsion one night after exposure to intensely cold weather. The spasms were on the right side. They recurred at intervals for a year, always on the right side, and she gradually began to lose power on this side. When about nine years old the convulsions became general, but they began on the right side. They have become more numerous, and she has had as many as fifteen in a day, and even four or five in an hour. *Status præsens:* Dull, stupid-looking girl; marked spastic hemiplegia of the right side, arm and leg rigid. Fingers strongly flexed in the hand. Heart normal.

Morbid Anatomy. Although the clinical features of infantile hemiplegia are as well characterized as those of infantile spinal palsy, our knowledge of the pathological conditions on which the former depends is, in comparison, still very defective. As in hemiplegia of adults, the lesions are variable, and the symptoms may be produced by any destructive process in the cortico-spinal section of the motor tract. It is surprising how few are the observations made shortly after the onset of the paralysis. The great majority of the post-mortems have been made after the hemiplegia has lasted for months or years, when all trace of the primitive lesion has disappeared.

I have analyzed the records of ninety autopsies in cases of hemiplegia coming on in infancy or childhood. The majority of these are contained in the articles of Cotard,[1] McNutt,[2] Gaudard,[3] Richardiere[4] and Wuillamier,[5]

[1] St. Petersburger med. Wochenschrift, 1887.

[1] Cotard: De l'atrophie partielle du cerveau. Paris, 1868.

[2] Loc. cit. [3] Loc. cit.

[4] Etude sur les Sclerose encéphaliques primitive de l'enfance. Thèse de Paris, 1885.

[5] Loc cit.

but I have, as far as possible, referred to the original cases, and have been able to extend the list of the forty-eight autopsies analyzed in 1886 by Wallenberg. The right hemisphere was affected in 39 cases, and the left in 51. It is interesting, as bearing upon the prognosis, to note in seventy cases the ages at which death occurs: under two years, 4; between second and fifth year, 10; from fifth to tenth, 8; from tenth to twentieth, 18; from twentieth to thirtieth, 12; thirtieth to fortieth, 4; fortieth to fiftieth, 8; above fifty, 6. I have excluded all cases of hemiplegia coming on after the fifteenth year, and, in the great majority, the onset dated from convulsions in the early years of life.

The lesions may be conveniently grouped under three headings:

1. *Embolism, thrombosis and hemorrhage.* In this group, comprising sixteen cases, the patients did not long survive the attack, and a study of the conditions found post-mortem might be supposed to throw considerable light on the nature of the initial lesion. In the cases of Gibb,[1] Vernois and Valleix[2] the condition was congenital. The mother, in Gibb's case, had received a blow on the abdomen, and the child was stillborn, with rigidity of the limbs on the left side. There was a clot in the right hemisphere above the ventricle. In the cases of Vernois and Valleix the labor was difficult, and the paralysis existed from birth. The children lived for forty-nine days and three and a half months respectively, and, in both, extravasation existed in the neighborhood of the ganglia. In the cases of Wrany-Neureutter,[3] Taylor,[4] Callender,[5] Kelly Johnson,[6] Barlow,[7] there was heart disease, with embolism of the middle cerebral artery. A case of Henoch's[8] was also embolic. In two cases of Callender,[9] in one of Lewkowitsch, and in one of Reimer, there was hemorrhage. In a case of Abercrombie,[10] the right Sylvian artery was plugged by a firm thrombus. In Case XII. of a series of aneurisms of the larger cerebral arteries, which I reported from the Montreal General Hospital,[11] a boy of six years, with left hemiplegia, there was hemorrhage into the longitudinal fissure, and laceration of the median surface of the right hemisphere, caused by rupture of an aneurism of the right anterior cerebral artery. In a case of Dulles,[12] in a child of six months, there was hemorrhage into the ventricles.

Thus, of the sixteen cases, there was plugging of a Sylvian artery, usually embolic, in seven, and hemorrhages in nine. In striking contrast to the majority of the cases of infantile hemiplegia, is the significant fact that in this group the age at onset is high. Excluding the three congenital cases, there was only one child under three years, while ten were over six.

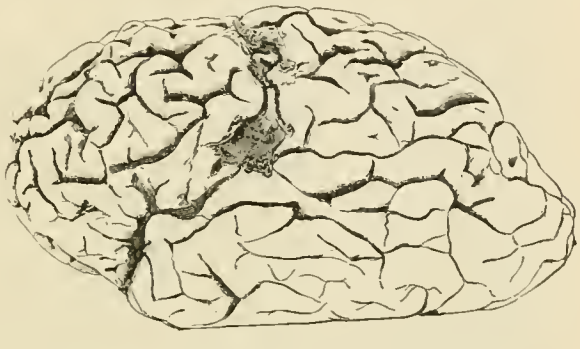
2. *Atrophy and sclerosis.* In fifty cases there was wasting with induration, either of groups of convolutions, an entire lobe, or, in some cases, the whole hemisphere was affected.

The following cases from the institution at Elwyn illustrate this condition in a typical manner:

Male, æt. sixteen years. Family history good. During measles when a child, he became paralyzed on the right side, and had aphasia. He regained partially the use of the leg, but did not recover speech. There was complete loss of power in the arm. He had repeated convulsions, in one of which he died. There was no sensory disturbance.

The only lesion found was in the left hemisphere. The brain was of full size, and looked natural; the membranes stripped off readily, except in the Rolandic region on the left side, where the pia mater was greatly thickened and adherent. As shown in the cut, Fig. 1, which is taken

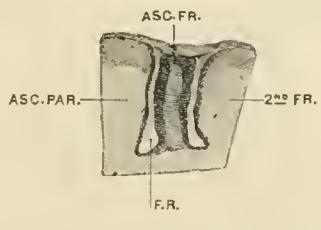
FIG. 1.



Left hemisphere, showing sclerosis in the Rolandic region.

from a photograph by Dr. Wilmarth, there is a depression in the neighborhood of the fissure of Rolando, and the fissure itself is not evident except at its upper third. So far as can be made out, the ascending frontal convolution in the greater part of its extent is atrophic, reaching to its lower end, but above there is at least half an inch unaffected. The central portion of the ascending parietal is also involved. From these regions the thickened membranes could not be removed without tearing the brain substance. The paracentral lobule, the third frontal and the insula did not appear to be affected. The cord, unfortunately, was not examined.

FIG. 2.



Section through the sclerosed area. *Asc. Fr.* Ascending frontal gyrus. *Asc. Par.* Ascending parietal. *2d. Fr.* Base of second frontal. *F. R.* Fissure of Rolando.

Sections across the sclerosed area, Fig. 2, show a complete atrophy of the ascending frontal gyrus and of the contiguous surfaces of the adjacent convolutions. The pia is thickened and closely adherent, particularly where

it dips down to the top of the wasted convolution. In the fissure of Rolando, a loosely arranged connective tissue, containing numerous bloodvessels, unites the opposed pial membranes. At the bottom of the fissure there is a wide sulcus, containing several large veins. In the shrunken ascending frontal convolution three layers of tissue can be readily distinguished, even with a low-power lens: (1) Beneath the pia is a narrow layer, resembling closely the normal first layer of the cortex, a granular matrix with a few nuclei arranged centrally, and, here and there, spaces, probably vascular. Bloodvessels pass through this part from the meninges. (2) A wider, more loosely arranged layer, with numerous nuclei and distinct fibres, among which are small arteries with thickened walls and dilated capillaries. In the deeper portion of the gyrus there are irregular spaces, some of which are large enough to be seen with the naked eye. (3) A central stem, composed of a close network of fibres, looking a little more condensed than the ordinary white matter, with scattered nuclei and a few bloodvessels.

The contiguous portions of the ascending parietal and second frontal convolution present essentially the same change. Although the entire gyrus is involved, the process is chiefly cortical and has resulted in the entire destruction of the gray matter.

I have recently had an opportunity of examining a second specimen at the Elwyn Institution with Dr. Wilmarth—a case of right hemiplegia with idiocy and epilepsy. The brain looked well formed; the meninges were normal. On the posterior part of the first left frontal, about three-quarters of an inch from the fissure of Rolando, there was a depression, over which the membranes appeared normal. The base of the first and the top of the ascending frontal gyrus had an opaque-white appearance, contrasting strongly with the surrounding tissue. On section this was seen to be an area of induration passing into the cerebral substance for at least an inch, and cutting with great resistance. A second opaque-white block existed in the hinder convolution of the quadrilateral lobe. On the left side there were two of these masses, one in the lower occipital convolution, and the other in the supramarginal. These masses were firm, opaque-white in color, the pia over them not thickened and the contour of the convolutions not destroyed. The examination of the brain has not yet been completed, but the blocks correspond to the description given by Bourneville and other French writers of the sclerose tuberuse.

To the French writers we owe much of our knowledge of cerebral sclerosis. Cazanvielh,[1] in 1827, described twelve cases under the term agénése cérébrale. Bourneville[2] has recorded a number of observations from the Bicêtre, while Cotard,[3] Jules Simon,[4] Richardière,[5] and Delhomme[6] have more recently written monographs upon the condition. In clinical features the great majority of the cases conform to the description of infantile hemiplegia.

The skull may be flattened on the affected side, and it is not uncommon to find it very broad and prominent above the mastoid processes. In several of the cases the bone on the affected side has been greatly thickened. The dura is usually closely adherent, and osseous plates have been found, which, in Bell's case,[1] were so extensive that the right hemisphere seemed enclosed in a second bony casing.

The arachnoid is turbid and thickened, and the amount of cerebro-spinal fluid excessive. The pia mater is often so thickened and adherent that, on removal, portions of the cortex come away, leaving a roughened surface, and in these cases the condition suggests a meningo-encephalitis. This localized thickening and adhesion of the pia to the sclerosed convolutions is well illustrated in the specimen just described.

The sclerosis is usually diffuse and involves either an entire hemisphere or a single lobe, or it may be confined to one or two convolutions. In a few cases it has been in patches—insular. Nodular projection of sclerosed tissue (sclerose hypertrophique) may occur over the surface. The affected convolutions are small, of a grayish or gray-yellow color, often with a stippled, pitted surface, to which the pia adheres firmly. In contrast with the neighboring normal gyri, the appearance is very striking and characteristic. The reduction in size of the affected hemisphere may amount to a third of the bulk. In one case the atrophied hemisphere weighed 260 grains, the normal 1007 grains. The tissue may be a mere shell over a dilated lateral ventricle, as in the cases of Baud[2] and Piorry. In many cases anfractuosities and small cysts have been found in and about the sclerosed tissue. Some of these cysts are evidently the result of old hemorrhages, as hæmatoidin crystals have been found in the walls. This is particularly the case with cysts in the neighborhood of the basal ganglia. In all of the fifty cases the Rolandic area was involved to a greater or less degree, in some cases affected alone, as in the brain figured; in others, involved in a widespread process. Undoubtedly the motor region, the area of the cortical distribution of the middle cerebral arteries, is most often affected, but this is not always the case.

Thus it is interesting to note the distribution of the lesions in ten specimens of sclerosis of the brain in the Museum of the Elwyn Institution.

I. R. H. Superior parietal lobule, patch ½ x ¾ inch, depressed meninges adherent.

II. R. H. First and second frontal. Occipital. L. H. Occipital lobe almost destroyed. Superior parietal, posterior half. Anterior two-thirds. First frontal, second frontal, slightly.

III. R. H. Cuneus. First frontal, extensive; gyrus fornicatus. L. H. Gyrus hippocampus, lingual, and occipital. First frontal slightly.

IV. R. H. Occipital lobe, outer aspect; supra-marginal; occipital end of first and second temporals; cuneus slightly. L. H. Temporal lobe, leaving the first untouched; supra-marginal and the entire angular group.

V. L. H. Gyrus fornicatus almost destroyed. Cyst on the middle of first frontal. R. H. Insula smooth; gyri not evident. Posterior half of first temporal; Sylvian ends of both central gyri. Middle portion of first and second frontal and posterior part of third frontal; gyrus fornicatus.

[1] Archives Générales, 1831.
[2] Quoted by Gaudard.

VI. L. H. Normal. R. H. Supra-marginal and angular gyri, encroaching on occipital; posterior third of first, second and third frontal.

VII. Blocks of induration. Sclerose tubereuse scattered over both hemispheres.

VIII. L. H. Normal. R. H. Temporal, parietal and occipital convolutions uniformly sclerosed; not a normal looking gyrus in any of these lobes. Frontal lobe quite natural looking; occupies more than three-fourths of the hemisphere. Patient was an epileptic; no paralysis.

IX. The case given in full. R. H. Normal. L. H. Sclerosis of ascending frontal and part of ascending parietal.

X. R. H. Nodular sclerosis, first frontal and base of ascending frontal. Patch on posterior gyrus of quadrilateral lobe. L. H. Patch on lower occipital, second on supra-marginal gyrus.

Dilatation of the lateral ventricle on the affected side is frequently mentioned; the basal ganglia may be flattened. In all the recently reported cases a descending degeneration of the pyramidal tract is described. In the cases of extensive atrophy of one hemisphere the opposite hemisphere of the cerebellum has been found smaller. The condition of the vessels has not attracted sufficient attention. In two cases Jendrássik and Marie found important changes in the walls of the cortical arteries to which we shall again refer.

3. *Porencephalus.* Associated as this condition invariably is with atrophy, of which it is indeed only a final result, to consider it separately is not strictly correct, and yet precision may well yield to the manifest convenience of grouping together for analysis the cases which present this lesion. Porencephalus represents a loss of substance in the form of cavities or cysts, situated at the surface of the brain, either opening into or bounded by the arachnoid, and often passing deeply into the hemisphere, reaching even to the ventricle. It was present in twenty-four of the ninety autopsies in hemiplegia. In eighteen of these cases the onset of the paralysis was noted. In six it was congenital. In eleven the hemiplegia came on in very early life after convulsions. In one it appeared to be the result of a fall at the age of two years. In six of the cases death occurred before the tenth year; in five between the tenth and twentieth year; in five between the twentieth and thirtieth, and in eight after this age. The extent of the defect was very variable, from a few convolutions to half a hemisphere. In all of the cases the motor region was involved to a greater or less extent. Although occurring in other parts of the brain in the great majority of cases the districts supplied by the middle cerebral arteries are affected. It is worthy of note that this condition usually corresponds with definite areas of vascular distribution.

DIAGNOSIS.—The more frequent onset with convulsions, the hemiplegic character of the palsy, the absence of rapid wasting of the affected muscles and the retention of electrical reactions are features of the early stage of the disease sufficiently well characterized to exclude, in most cases, infantile spinal paralysis. The rigidity of the muscles, the increase in the reflexes, the gait, the distribution of the residual palsy, the impaired intellect, and the frequent onset of convulsions clearly characterize the later stages.

There are cases, however, which present difficulties, owing to irregular distribution of the paralysis. Thus the following case of spastic crural monoplegia is probably, from its character, of cerebral origin.

Case XXV.—James H., æt. five months. I. P., 125. Healthy when born and until two and a half years old, when, for two weeks, he had fever, which was preceded by screaming spells. He seems to have pain in the right leg, and the back seemed painful and stiff. Then rigidity appeared in the left leg. During the attack he was delirious. The arms were never affected. There was no loss of sensation at any time. The condition is now confined to the left leg. The foot can neither be flexed nor extended, and is shorter than the right. Cannot lift the thigh. Can flex the leg slightly. Cannot stand on left leg. There is a difference of one and three-quarters inches in circumference of the legs, and of one and a half inches in that of the thighs. The reflexes are increased.

In the following case there was, at first, right hemiplegia, with the involvement, also, of the left arm, a distribution suggestive of spinal palsy, but the history clearly shows that the origin was cerebral.

Case XXVI.—Mary J., æt. two years and a half. H., 345. The second of three children; others well. Family history good. Mother fell three days before confinement, and was delivered of the child prematurely at eighth month. Birth normal. About May 30th, when two years old, was peevish and whining for a time, and then had convulsions, in which the mouth and face were twisted to the left, and she moved hands and arms. Both arms were paralyzed; and the right leg, after the attack. It was five weeks before she began to use the left hand, and she has never regained power in the right. She began to use the right foot in about two months. *Status præsens:* Cannot walk, but slides along on her buttocks. Mind is deficient; cannot talk; but understands what is said to her. Cranium microcephalic; biparietal diameter, 4.5 inches; occipito-frontal, 6; circumference, 17½. Slight internal squint. Rigidity of right leg at knee. Right hand is clenched, fingers extended with difficulty; hand seems slightly smaller than the left; no difference in forearms. Right hand gets cold and blue at times.

At the Elwyn Institution there is a remarkable case which must be regarded, I think, as one of post-hemiplegic epilepsy. All trace of the hemiplegia has disappeared, but there remain slight wasting, increase of the patellar reflex and occasional attacks of Jacksonian epilepsy, to indicate the nature of the original trouble. As the fits became general, and were aggravated at each menstrual period, oöphorectomy was performed, with relief at first; but, as might be expected, they have returned.

Case XXVII. (Elwyn series).—Annie S., æt. twenty-three years. Inmate of institution for one year. Mother in an insane asylum. When between three and four years old, fell and, for a long time after, could not walk; weakness of the left side. In one history of this case it is stated that the paralysis came on after scarlet fever. Had spasms at the age of twelve. Always began in arm, and for a long time were in the arm alone. Had the spasms worse at menstrual period, usually three or four, either just before or just after the period. Oöphorectomy was performed two years ago, February, 1886. Better for a year. Is a well nourished girl; gives a good account of herself. Left arm is smaller than right. Left

forearm, 9 inches; right, 9½. Wrist: left, 6½, and right, 7. No spasm, no rigidity; movements perfect. Left leg smaller than right. Calf, 12⅞. Right calf, 14⅜. Foot; length: left, 8½; right, 9. Left knee-jerk —. No ankle clonus; no heart lesion. Every time the fit begins in the left arm, the fingers are drawn up and the arm gets stiff. She has then to lie down on the sofa, and they become general; sleeps after them; has often vomiting. Has not had an attack since February, 1888. At first, while in the institution, they recurred for a number of months with regularity.

In certain *cases of cerebral tumor* the symptoms are those of spastic hemiplegia. Seeligmüller[1] records such an instance of tubercle of the meninges, beginning with convulsions and fever, with left hemiplegia and contractures in hand and foot; and I have described a case of glioma[2] in a girl of thirteen years, in whom spastic hemiplegia had lasted for some years, and who had Jacksonian epilepsy.

Paralysis of the face and of the upper extremity may result from the application of the forceps; the latter more commonly from the manipulations of the accoucheur. These *obstetrical paralyses*, as Duchenne[3] called them, could rarely be confounded with those due to cerebral causes. They are fully considered by Nadaud,[4] and Budin[5] has recently given an excellent description of the brachial palsy.

PROGNOSIS.—Parents are naturally intensely anxious as to the prospects of a child attacked with hemiplegia. As a rule, the younger the subject the greater the liability to serious and permanent damage. The nature of the lesion doubtless has an important influence, vascular obstruction more favorable than meningo-encephalitis, and the latter than tumor, but the diagnosis of the exact condition is by no means always easy. Of the bodily defect, about which the greatest uneasiness is displayed, we can almost invariably predict great improvement, particularly of the leg. Perfect recovery of the arm is rare, of the face more frequent. The development of post-hemiplegic movements is a bad omen, as such cases are more likely to have epilepsy, which constitutes one of the most serious sequences of the disease. Not only are the attacks dangerous in themselves, but they undoubtedly tend to aggravate existing mental defects. They may not develop for some years after the onset of the paralysis and may be deferred till the period of puberty. More distressing still to the relatives is the enfeebled mental state which so often follows infantile hemiplegia. As the records of the Pennsylvania Institution for Feeble-minded Children at Elwyn show, the percentage of the cases due to this cause is by no means small. Training does much for them, but for too many the outlook is not hopeful, and, as Merklin states, even when in childhood they escape imbecility, they are very liable in adult life to become the subjects of psychoses. *Quoad* life the prognosis is good, as shown in the post-mortem reports of ninety cases, in a large proportion of which the age at death was over twenty years.

ORIGINAL ARTICLES.

A CASE OF EXTRAUTERINE PREGNANCY; EMBRYO DESTROYED BY A 20 MILLIAMPERE CURRENT WITHOUT INTERRUPTIONS;

Together with Remarks on the Best Manner of Using Electricity for this Purpose.[1]

BY A. H. BUCKMASTER, M.D.,
OF BROOKLYN.

ON the 16th of February, 1888, Dr. A. J. C. Skene requested me to see Mrs. C., for the purpose of destroying an embryo that was developing outside of the uterus.

The patient was an Englishwoman, twenty-nine years of age, and gave me the following history: She had been married four years; had one miscarriage two years ago, and has a child three years of age. Her menstrual periods recur regularly, and have always been plentiful. She was troubled with dysmenorrhœa previous to her marriage, but since then has been free from pain.

Last October the patient changed her residence, and menstruated the latter part of that month. She did not menstruate the following month (November), and thought she was pregnant. She had never passed over a period except when *enceinte*, and was much troubled with nausea and bladder irritation, symptoms she had experienced previously only when bearing child.

On the 26th of December (the day on which the Christmas feast was held), while assisting in the preparation of the dinner, she had what she described as a "very queer turn." She said: "I never felt better in my life than I had that morning." A short time before dinner she became nauseated and went to the bath-room to vomit. She suddenly felt a violent pain in the "pit of the stomach," heard a ringing noise in the ears and fainted. She lay on the floor groaning and did not have strength enough to call loudly for assistance. She was found in this condition by her husband and removed to her bed. It is said that her face was very pale, and she fainted at each attempt to sit up. She was very thirsty, and "thought the doctor cruel" in that he did not permit her to drink all the water she desired.

Dr. Francis W. Bowron, the family physician, was sent for, and from him I obtained the following history:

"On December 26th I was summoned in great haste to Mrs. C., who was reported to be dying. I found her in a condition of collapse, pulseless at the wrist, the lips bloodless and the face pale and ghastly in expression. The heart was irregular and intermittent, and there was great pain in the abdomen. She was treated as a case of internal hemorrhage and in the evening rallied. The next day the symptoms of pain and shock recurred, and on the 28th there was again an attack, but of much less

[1] Read before the New York Academy of Medicine, Section on Obstetrics and Gynecology, May 24, 1888.

severity than before. On the 12th of January there was a recurrence of these fainting spells, also on the 13th and 14th of January. Dr. Skene saw the patient, who had been rapidly increasing in size, on the 14th of February, and made the diagnosis of extrauterine pregnancy. He recommended that Dr. Buckmaster be called in to use the electric current for the destruction of the fœtus. The increase in size of the patient's abdomen was arrested after the first treatment by Dr. Buckmaster. The patient is now her natural size and in fair health."

The following notes were obtained from Dr. Skene:

"I saw Mrs C., in consultation with Dr. Bowron, on the 14th of February. I found the lower part of the abdomen enlarged. The right iliac region was the most prominent, and there was slight tenderness on touch. Dulness on percussion from the right ilium across the lower part of the abdomen and upward to somewhat more than half the distance to the umbilicus. On the left side the dulness did not extend upward more than two inches. An ill-defined mass, elastic to the touch, was distinctly traceable on the right side. Vaginal examination showed that the uterus was crowded forward toward the pubes, and that it was somewhat enlarged and softened. The sac of Douglas was occupied by an elastic mass, in which fluctuation could be detected, and which felt not unlike a small ovarian cyst, and seemed to be part of the tumor felt in the right iliac region, from which the uterus appeared free.

"The diagnosis was between an ovarian cyst fixed on the right side and an extrauterine pregnancy. Taking the physical signs with the clinical symptoms a diagnosis of the latter condition was made. The general impression left on the mind of the examiner was that, without doubt, it was a case of extrauterine pregnancy."

I saw the case with Dr. Bowron on the 16th of February, and found the conditions as just described by Dr. Skene. The patient stated that she had progressively increased in size during the past three weeks.

After carefully considering the different methods for destroying the fœtus, none of which seemed altogether satisfactory, I determined to use the galvanic current without interruptions, for reasons that will be stated later.

The current[1] was gradually increased by means of a rheostat until a strength of 20 milliampères was reached—no attempt to go further than this was made, as the patient felt some pain. After maintaining the current for ten minutes it was gradually decreased. The patient experienced no shock. For the abdominal electrode was used a large *plaque* of clay with sixty-four square inches of contact; the vaginal electrode was of steel covered with wet absorbent cotton. I was careful to press down on the abdominal electrode as much as the patient could bear, and also to raise the electrode in the vagina so that the current could be in as intimate relation to the fœtus as possible. I regard this as important, because the fluid about the fœtus offers so much resistance to the passage of the current. At the end of the *séance* the patient declared herself much relieved from the pelvic pain that had greatly annoyed her. I attributed this relief to the sedative influence of the positive pole. I had used the positive pole in the vagina anticipating this result.

Six days after the first treatment the patient was again seen and her physical condition found to be much improved. The appetite had returned and the abdominal circumference had markedly decreased. Both the patient and her friends were delighted with the result. The physical examination was very satisfactory. The cyst seemed to have lost much of its fluid contents. I felt quite sure that the child was dead, but as the thorough examination started up the old pelvic pain, I made another electrical application. The third, and, subsequently, three more applications were made for the relief of this pain, at intervals of about six days. None proved so efficacious as the first.

At the third treatment the measurement around the abdomen had increased about an inch, and six days later was half an inch more, but after this, the circumference measurement steadily decreased. Toward the end of February and also at the end of March, the patient menstruated.

The patient was seen three months after the first treatment and was in very good health. A hard mass can still be felt by making a vaginal examination, and there is a slight tenderness about it.

The questions which would naturally suggest themselves with this and other cases of this kind are:

1st. *Was the diagnosis of extrauterine pregnancy warrantable?*

We had the subjective symptoms of pregnancy already enumerated: nausea and irritable bladder, and these symptoms were of special significance because they had existed with the previous pregnancy and at no other time. Coupled with the cessation of the menstruation, the diagnosis of pregnancy would be highly probable. The uterus, although somewhat enlarged, did not correspond in size or condition of the cervix with the pregnant uterus of this period. It was pushed forward, and the fundus could be felt above the pubes. In the sac of Douglas was a large fluctuating mass rapidly increasing in size. About the time the second period was due the patient suffered from cramp-like pains followed by signs of internal hemorrhage.

From the foregoing facts the case is about as clear as possible, except that there is no definite statement as to the casting off of the decidua, but we know it is often impossible to utilize this sign.

2d. *Was the child living when the electricity was first applied?*

The rapid increase in size observed by the doctor and the patient during the latter part of January and

[1] A fifty cell chloride of silver battery, made by Mr. Barret, was used.

during February, after the symptoms of a peritonitis had subsided, indicated, by exclusion, a living ovum. Conversely we supposed the death of the ovum from the fact that the tumor decreased in size immediately after the treatment. It not only decreased in size but changed in character, losing its elastic feeling on account of the absorption of the fluid contents. It has been claimed recently that the placenta continues to grow after the death of the fœtus, but as we have seen no corroborative evidence, it is not worth consideration at present.

3d. *Is the uninterrupted current the best means for destroying the fœtus?*

I shall say but little as to the advisability of the use of electricity. So many eminent Americans have advocated its employment, that it has justly become known as the American plan of treatment. Although an Italian, Bachetto, first used the current for the destruction of the fœtus, he used it in connection with puncture, a procedure which indicates that he had no conception of the advantages of this potent agent. So, as Dr. Garrigues very justly remarks, the honor of priority may be justly claimed by America. Dr. T. G. Thomas, whose experience has been very large, says, in his characteristically forcible manner, "It has these great advantages: if an error of diagnosis has been made, this remedy will do no harm; if the diagnosis be correct, experience proves it to be sufficient in its effect; . . . and it requires no surgical skill in its use."[1] Many cases will undoubtedly appear as the literature of the subject expands, in which, after cutting into the abdomen, it will be found impossible to complete the operation.[2]

Three methods are in use for the destruction of the ovum by electricity.[3] In the *first* method we may mention the use of the primary or secondary current of the ordinary faradic machine. This method is the one that has been most commonly used. For the *second* method we use a galvanic current of from ten to sixty milliampères with interruptions; and in the *third* class we consider the use of the galvanic current of effective intensity without interruptions, and increased or diminished gradually.[4]

The first method depends for its effectiveness on the shocks produced by the rapid breaking of the current by the magnet. The current strength is insignificant, and is usually obtained from two cells. Landis[1] applied the poles of a Flemming faradic battery against the shoulder and opposite rump of a newborn rabbit, and then used the full force of the battery for five minutes, and yet the rabbit recovered. A newborn rabbit is killed by very slight violence, and it would appear from this and other experiments, which he made on minnows and beetles, that embryonic life is not so easily destroyed by this agent as one might imagine.

This idea will be confirmed in reading the very interesting history of a case of extrauterine pregnancy by Dr. Ely Van De Walker.[2] He used a powerful induction coil. He says:

"The irritation from one induction coil was such that it could not be tolerated elsewhere about the body for a moment . . . . . She had ten *seances* of half an hour duration each, on the same number of consecutive days . . . . . On the pelvic mass there was no evidence that I had made any impression whatever. Its size remained the same, and its resistance to the touch, or what I would prefer to term tension, was unchanged." He determined to prolong the treatment to an hour. "We did so for three successive days, using the full strength of the induction coil. On the third day we found evidence that the electricity was accomplishing its work."

The danger of producing rupture of an already weakened tube has been pointed out, but some of the recent writers are disposed to belittle this risk because we have no deaths directly traceable to it as a cause. We have had as yet too few cases reported to draw any such deduction, and the dangers of a possible rupture offer to my mind a valid objection against the use of the faradic current.

By the second method, in which a comparatively strong galvanic current is used, the advantages of the first method are rendered greater, and the danger of rupture is also increased. This is so true that I doubt if the second method is justifiable with our present knowledge of the subject. Dr. A. J. McCosh, speaking of a case treated by this method some time ago, says: "The contraction of the legs and abdomen was very energetic when the current was interrupted."[3]

On February 15, 1887, at a meeting of the Obstetrical Society of New York, Dr. Paul F. Mundé remarked that he had reported a case two years before in which one pole was introduced into the rectum, and twenty four cells were used with interrupted shocks; the fœtus was killed, but the patient received such a severe shock that she was collapsed, and was restored only after receiving repeated hypodermatics of brandy, ether, etc.[4]

We use the third method precisely as we use the galvanic current for the destruction of a fibroid

[1] Trans. Amer. Gyn. Soc., vol. lx.

[2] See autopsy by T. G. Thomas, Trans. Amer. Gyn. Soc., vol. viii. p. 167.

[3] The use of the static form of electricity is not considered because of the difficulties in the way of its application.

[4] At the meeting of the Section before which this paper was read the writer stated that he believed his case was the first one in which the current had been applied in the manner above mentioned. He finds, however, that in Dr. Janvrin's case, which antedates his, it was so applied at Dr. Rockwell's suggestion.

tumor. That a current of twenty milliampères strength has a profound effect upon the cellular structure is shown by experiments that I made upon the heart of a living dog,[1] in which it was observed that the striæ of the heart's muscle became granular and indistinct. I speak of this to indicate with what a potent agent we are dealing, and also it gives us a reason to understand how the current is effective.

In the case reported by the writer, twenty milliampères of current apparently caused the death of the embryo; but if this amount of current should prove for any reason inefficient, or if instant results are desired, it may be increased up to 100 or 150 milliampères if necessary, when there could be no doubt of the result being attained. Sixty to eighty milliampères are often borne without discomfort by the patient without an anæsthetic. The fluid about the embryo offers so much resistance that the electrodes should be brought as near the child as possible, and to accomplish this the abdominal electrode should be pressed down and the vaginal electrode raised under the mass.

The writer has not considered the question of the use of electricity in connection with puncture of the sac, because he believes, from the experience of reported cases, that this procedure is more dangerous than laparotomy.

To recapitulate in regard to the three methods of using electricity for the destruction of the fœtus:

1. The faradic current is not certain in its action and not without danger. It must be used a number of times and for prolonged *seances*.

2. The interrupted galvanic current is more effective than the faradic and by far the most dangerous of the three. It should never be used, because the other methods will accomplish all that is claimed for it, and it is in itself exceedingly dangerous.

3. The uninterrupted galvanic current will accomplish at once the death of the fœtus; it will relieve the intense pelvic pain by the sedative influence of the positive pole placed in the vagina; *it is without danger*.

In the application of this method, all that is necessary is any electric battery containing enough cells, connecting cords, a rheostat and a vaginal and an abdominal electrode.

The battery used by the writer was the fifty cell chloride of silver battery made by Mr. John A. Barrett. It weighs but eleven pounds and is 11x7x6 inches, so that it can be easily transported. Mr. Barrett has also invented a dry rheostat which can be carried in the pocket and which will prove very satisfactory if the current strength desired is not greater than seventy-five milliampères.

The abdominal electrode consists of two parts, a plate of copper and under it a pad of ordinary cotton batting, two inches thick when dry. The latter should be applied so wet that the water drips from it. The copper plate may be procured from a plumber at the cost of a few cents, and cut with tinners' shears to the shape desired. A hole should be punched through it, and then by means of a piece of copper wire it can be fastened to the connecting cord. For the vaginal electrode almost any of those in the market, covered with a layer of wet cotton, will answer the purpose, and if they are large enough there need be no fear of cauterizing the vagina.

The following rules for the application of the electricity may be followed with advantage:

1st. Use the positive pole for the vaginal electrode.

2d. The electrodes being in place and the connections secure, permit the current to increase in strength gradually, by means of the rheostat, until the patient complains of pain.

3d Press up the vaginal electrode and downward on the abdominal electrode, as much as the patient can bear.

4th. If the immediate destruction of the fœtus is imperative and the patient cannot bear more than twenty milliampères, use an anæsthetic and pass a 100 milliampère current.

5th. Decrease the current gradually at the expiration of fifteen minutes.

[1] Prize Essay read before the Alumni Association of the Long Island Hospital Medical College, 1888.

REPORT OF A CASE OF SEVERE HEMORRHAGE FROM THE STOMACH.

BY VICTOR C. VAUGHAN, M.D.,
PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN.

THE following case presents some features which are probably worthy of record:

April 28, 1888, about 6 P.M., I was called to see Mrs. S., the wife of a brother physician. I found that she had not been feeling well during the day, had excused herself from the supper table, and had walked into the hall, when she fell and began to vomit blood. A small quantity of the blood was thrown upon the floor, but the greater portion was received in a bowl, and this measured one pint. I found the patient very weak and faint, and I immediately injected into the arm twenty minims of Wyeth's fluid extract of ergot, and applied ice over the stomach. As soon as she was able to swallow, we gave her small bits of ice.

For nearly an hour she seemed fairly comfortable; then she began to complain of a sensation of fulness in the stomach, and soon blood poured from the mouth and nose. All of this hemorrhage was caught in a bowl, and it measured a full quart. It was bright red in color and clotted in the bowl. The reaction of the blood was not ascertained. The injection of ergot was repeated, the dose being in-

creased to thirty minims. The application of ice over the stomach was made interruptedly, with the hope of securing the full effect of cold upon the contractility of the bloodvessels.

Although the patient remained unconscious for some time after this hemorrhage, there were occasional attempts at vomiting, and after about thirty minutes a third vomiting of blood occurred. The amount of blood thrown up at this time could not be accurately determined, as it was received in a bowl containing water. This time the blood was dark and clotted, and from this we inferred that there had been no fresh hemorrhage, and that the blood now emitted had been poured into the stomach along with that which had been previously vomited. After a few minutes the patient regained consciousness, but she could not be moved in the slightest manner without becoming faint, and it was only after three days that her clothing could be removed, and fully two weeks passed before she could open her eyes without having the sensation of fainting. We did not dare to give stimulants to any extent for fear of raising arterial pressure, and thus causing a renewal of the hemorrhage.

The question of nourishing our patient now became a very important one. Feeding by the bowel was thought of, but the idea was dismissed on account of the existence of painful hemorrhoids. Indeed, it was found some days later that an attempt to wash out the lower bowel was followed by violent and painful spasmodic contraction of the sphincter ani, which placed the patient in an alarming position, and at another time an attempt to introduce a suppository was followed by similar symptoms.

After consultation, we determined to try some artificially digested food. A peptone was first tried, but its disagreeable taste caused nausea, and threatened to produce vomiting, which might have proved disastrous. Having used the beef peptonoids of Reed & Carnrick successfully in the treatment of cholera infantum, I determined to try it in this case. It was not objectionable to the taste and did not distress the stomach. For three days our patient was given no other food: then some of Carnrick's soluble food was added, and these preparations constituted the sole diet for three weeks. No medicine was given at any time, save a few drops of the fluid extract of cannabis indica, a few evenings, as a cerebral stimulant, in order to relieve the anæmic headache, which gave trouble, and to induce sleep. This medicine acted very pleasantly. Past experience with the patient in other forms of illness led us to abstain from the use of morphine, which had proven likely to cause nausea and vomiting.

The source of the hemorrhage in this case is of interest. Some eight years ago the patient had experienced a similar, but much slighter, hemorrhage. It was suggested at that time that the hemorrhage might be vicarious, as she had failed to menstruate, but in the present instance the physiological hemorrhage had been normal for some years, a period having preceded this hemorrhage from the stomach about ten days, and it may be stated here that there have been two normal periods of menstruation since the attack.

Although the patient's digestive organs have not been in the most vigorous condition, she had not before the attack complained of any special pain in the stomach, and she had during the year done full work as a teacher, besides considerable original work and writing. That she has a cirrhosed liver I think there can be no doubt, and I think that portal congestion, probably long continued, has had a large share in the causation of the hemorrhage from the stomach. However, the large amount of blood, and its bright red color, caused me to believe in the existence of an ulcer in the stomach. We know that such ulcers may exist without causing much distress.

THE INJECTION OF A SOLUTION OF COCAINE INTO THE URETHRA FOLLOWED BY DEATH.[1]

By J. HENRY C. SIMES, M.D.
SURGEON TO THE EPISCOPAL HOSPITAL OF PHILADELPHIA

A. M. was admitted into the surgical ward of the Episcopal Hospital on February 23, 1888. Age, twenty-nine years. English. He gave a history of having suffered from stricture of the urethra some years before, for which the operation of external urethrotomy had evidently been performed. At the time of admission there was some difficulty in passing water, and the urine, he said, "comes out of an opening between the legs." Upon examination there was found the cicatrix of a perineal section, having a small fistula communicating with the urethra. The urethra was examined, and the existence of a stricture was ascertained, situated about four and a half inches from the meatus. The stricture admitted a No. 11 French bougie.

Gradual dilatation, by means of sounds introduced every other day, was the treatment under which the patient was placed for two weeks. Favorable progress was made, and the the urethra now easily admitted a No. 20 sound. Internal urethrotomy was determined upon, in order to remove all hindrance to the passage of urine through the urethra, and permit the healing of the perineal fistula. On March 3d, the day I had intended to perform the operation, the patient complained of sore throat, had a slight chill, and there was a slight increase of temperature. This proved to be nothing more than a mild attack of bronchitis. On March 9th, he was feeling quite well, and I had him removed to the operating-room for operation.

Previously to performing internal urethrotomy, I have, for the past year or two, injected into the urethra a solution of muriate of cocaine, which has lessened the pain of the operation, although not

[1] Read before the Philadelphia Academy of Surgery, June 4, 1888.

completely rendering the parts insensible to the cutting. The strength of the solution used in my previous cases had been five per cent.

The man was placed upon the operating-table, one drachm of a twenty per cent. solution of muriate of cocaine was introduced into his urethra, by means of a long-nozzled urethral syringe which passed about four inches into the canal. The instrument had scarcely been taken out of the urethra when the patient made a foolish remark, the muscles of his face began to twitch, the eyes staring, pupils dilated, frothing at the mouth, face much congested, respiration interfered with, and ending in a violent epileptiform convulsion, lasting for some seconds. These convulsions were continued with increasing violence, several times a minute, the whole muscular system taking part in the spasms, requiring considerable force to keep him from falling off the table. The action of the heart was not much interfered with, and appeared only to be secondarily affected. It was the respiratory function that seemed first to fail, and then the heart's action became irregular and slow. The breathing was gradually more and more interfered with, the face—in fact, the entire surface of the body—became deeply cyanosed, the pulse slow, and at the end of twenty minutes from the first convulsion had ceased to beat. The man was dead.

The means employed to relieve the patient were all useless; nothing had any effect in controlling, lessening or in any way influencing the ultimate result, and I may say everything was promptly and efficiently done; the entire staff of resident physicians of the Hospital ably assisted me in my efforts, which unfortunately were futile.

The *post-mortem* was made by Dr. Grimm, Resident Surgeon at the Hospital. *Thorax*: Lungs normal, but much congested; heart normal, right side empty, left side filled with currant-jelly clots. *Abdomen*: Liver much congested; spleen presented on its surface several stellate cicatrices; kidneys much congested and also cicatrices similar to those seen on the surface of the spleen; they were thought possibly to be syphilitic in nature. The *urethra* was examined to ascertain if there had been a rupture made in introducing the syringe, but no such lesion was found. The *brain* showed the bloodvessels very much congested; its membranes on either side of the longitudinal sinus at the vertex, covering a space of two square inches, were thickened and closely attached to the brain-substance; this probably was the result of some previous inflammatory action.

The cases of poisoning by cocaine have been very thoroughly searched for and published by Dr. J. B. Mattison, of Brooklyn, in two papers, "Cocaine Dosage and Cocaine Addiction," February 15, 1887, and "Cocaine Toxæmia," January 15, 1888. In the first paper are reported four fatal cases due to this drug, and in the latter two more cases that resulted fatally. The cases in which symptoms of cocaine poisoning occurred with more or less severity, but not fatally, numbered in Dr. Mattison's first article over fifty and in his second paper over forty.

MEDICAL PROGRESS.

The Treatment of Migrainous Headache.—Dr. James Little, before the Royal Academy of Medicine, read a paper on migrainous headache. He said he was in the habit of directing the patient, when he awoke with any feeling of headache, to take twenty grains of the salicylate of sodium in a wineglassful of water, made effervescent by the addition of a dessertspoonful of the granular citrate of caffeine, and, if necessary, to take a second or even a third dose at intervals of two hours. The effervescing caffeine made the dose a very palatable one, which the salicylate alone was not, and probably rendered it more useful; but that the good effect was not due to the caffeine was proved by the fact that the author had seen it relieve persons who had previously used the caffeine alone without benefit. It did not appear to lose its effect, as a patient, to whom Dr. Little gave it more than two years ago, said she found it as valuable as when she first began its use.—*British Medical Journal*, June 9, 1888.

Resorcin in Laryngeal Tuberculosis.—Dr. Frohnstein of Moscow (in the *Rossk. Med.*), states that resorcin is an excellent means for the relief of the discomfort and pain of tubercular ulceration of the larynx. He applies a ten to twenty per cent. solution with a brush, and directs, besides, the inhalation of a two per cent. solution several times daily. He prefers resorcin to cocaine.—*Centralblatt für die Gesammte Therapie*, June, 1888.

The Physiological Actions of Strophanthin.—A series of experiments on curarized dogs, conducted by Popper, of Vienna, in the laboratory of von Basch, in which the action of strophanthin (Merck's) upon the arterial pressure, the pressure in the veins and in the pulmonary artery, and with reference to the relation of the heart to its nerves was investigated, led to the following conclusions:

1. The arterial pressure is raised. This is mostly to be referred to a change in the heart's work, for:

2. It occurs if the splanchnic nerves or the spinal cord, at the level of the first cervical vertebra, are divided before the intoxication.

3. The appearance of the exposed intestine negatives vaso-constrictor stimulation. While the arterial pressure is raised the surface becomes not paler, but rather redder.

4. The pressure in the veins conforms to the preceding. At the same time that the arterial pressure is raised, the venous pressure is either slightly increased or remains normal, or even diminishes.

5. The pressure in the pulmonary artery increases comparatively less than does that in the aorta. The relation between the aortic pressure and that in the pulmonary artery changes in favor of the former.

5. The irritability of the inhibitory fibres of the vagus disappears in the course of the intoxication; hence, at a certain stage, stimulation of the vagus causes no slowing of the pulse.

7. The irritability of the accelerator nerves remains intact throughout.—*Centralblatt für die mediniz. Wissenschaften*, June 2, 1888.

Melæna Neonatorum—In the *Deutsche medizin. Wochenschrift*, of May 31, 1888, Dr. Otto Fross reports a case of melæna neonatorum, in a female infant, with recovery.

Blood was copiously passed by mouth and anus. The treatment consisted in placing the head low, surrounding the extremities with cotton wadding and hot water bottles; placing an ice bag upon the abdomen for two hours at a time, with intermissions of an hour; hypodermatic injections of ergotin and of camphor (of each three-quarters of a gr. twice or three times a day); the administration of the liquor ferri sesquichloridi (one drop every two hours in iced milk), cold solution of albumen and alcohol. At two months the child was as well developed as its age warranted. Melæna neonatorum is a rare affection, occurring once in 500 births (Henoch), or in 1000 (Genrich).

Iodoform for Hæmoptysis.—CHAUVIN and JORISENNE (*Le Prog. Méd.*, No. 20, 1888) recommend iodoform in pulmonary hemorrhage. These are two formulæ:

Iodoform . . . gr. ¾.
Extract of gentian . q. s. to make one pill.
S. Three to five pills in twenty-four hours.

Iodoform . . . gr. ¾.
Tannic acid . . . gr. iss.
Extract of gentian . q. s. to make one pill.
S. Three to five pills in twenty-four hours.

—*Therap. Monatshefte*, June 1, 1888.

A Case of Intussusception of the Stomach.—PROF. CHIARA, before the Verein deutscher Aerzte in Prag, stated that Engel had reported the occurrence, at times, shortly before death, of the slipping of the larger portion of the stomach over the smaller, as a result of excessive peristalsis; but no report of a true intussusception of the stomach had hitherto been made, and the following case must be considered as unique of its kind. It was that of a woman, aged fifty-four years, who had died after having been under observation for twelve days at Pribram's clinic. Several weeks before admission into the hospital, in consequence of severe physical strain it was thought, she was suddenly attacked with pain in the epigastrium, bloody vomiting and diarrhœa. The manifestations promptly disappeared under treatment, but soon returned with vehemence, in consequence of which the patient came to the clinic of Prof. Pribram.

She was found to be much emaciated and jaundiced. A cylindrical tumor, of varying consistency and size, was detected in the pyloric region; there was marked peristaltic action of the stomach, occasional vomiting of bloody or bile-tinged masses, and diarrhœa, from which a diagnosis of ulcerative carcinoma of the pylorus was made. At the autopsy on the 11th of March, of last year, there was seen a partial intussusception involving the greater curvature at the pyloric area, induced by a polypoid adenoma of the mucous membrane, and reaching into the upper portion of the duodenum, which could be reduced by slight traction on the greater curvature; the upper portion of the duodenum was much dilated and greatly hypertrophied.

The partial intussusception of the stomach had given rise to stenosis of the pylorus, with its consequences. The clinical manifestations led to the conclusion that the ready reduction of the intussusception observed post-mortem must have existed during life, and the contraction of the greatly hypertrophied upper portion of the duodenum had apparently caused the occasional replacement of the intussuscepted part to its normal situation.

Prof. Pribram remarked in connection with the diagnosis that the evidence of a cylindrical tumor in the pyloric region, the occasional bloody vomiting rendered plausible the view of an ulcerating carcinoma of the pylorus, with marked peristaltic movement of the stomach, though the early appearance of bile in the vomit, the interval of relief and the period of the occurrence of the peristaltic action of the stomach occasioned some doubts as to the correctness of the diagnosis.

Pribram explained the recurrence of the invagination by the tumor lying in the lumen of the pylorus being forced into the duodenum by the violent vomiting in the expulsion of an impacted gall-stone, which was found at the autopsy.

As to the treatment, as the tumor was mobile, operative procedure might have been thought of, but for the high degree of emaciation and the suspicion that, in view of the existing jaundice, the liver also was carcinomatous; though, even with a correct diagnosis, with the ulceration of the bile passages which existed as a result of the cholelithiasis, the success of an operation would have been questionable. But early operative measures, that is, with a better nutritive condition and prior to the impaction of the gall-stone, might have afforded permanent recovery.—*Wiener medizin. Presse*, March 27, 1888.

The Treatment of Gall-stone Colic. — MR. JONATHAN HUTCHINSON recommends (*British Medical Journal*, June 30, 1888) the use of anæsthetics to full insensibility, kept up for a long time, both preceded and followed by opiates, as the best treatment for all forms of gall-stone colic. It does not matter whether the stone is impacted in the common duct or in the bowel; we can scarcely do better than prevent spasm and favor relaxation of the parts concerned. By these measures, he has, in several cases in which he had been called in with a view to operation, succeeded in quite removing symptoms which were very urgent.

Oxidizing Oils.—R. BENEDIKT and F. ULZER (*Ztsch. f. Chem. Ind.*), stimulated by a patent by T. H. Gray, have made experiments with cotton-seed oil by passing a stream of air through it at 200 degrees, with a view of oxidizing the oil. According to the length of time the process is continued the oil becomes more or less thick, and finally a gelatinous mass. The oil remained neutral; the reaction did not concern itself with the glycerin, but the action of the oxygen exerted itself upon the glycerides of the liquid fat acids contained in the oil, changing these partly to glycerides of oxyfat acids. The authors found the "Soluble Castor Oil," put up by a firm in Hull, to be oxidized cotton oil.—*Pharmaceutical Record*, June 15, 1888.

Hydrocele Neonatorum.—WICHSELMANN, in the *Archiv für Chirurgie*, Bd. 36, S. 627, comes to the following conclusion: Hydrocele in the newborn is more common than is generally known; it is mostly right-sided; it comparatively often communicates with the abdominal cavity, and probably develops in part in utero.—*Fortschritte der Medicin*, June 1, 1888.

A New Method of Gastrostomy with the formation of a Sphincter.—After gastrostomy has been successfully performed for an impassable stricture of the œsophagus,

and nourishment can be administered through the fistula, undesirable complication are apt to arise, in that the gastric fluids escape at the side of the canulas and tubes, giving rise to excoriations of the abdominal wall. The condition shows no tendency to improve, but, on the contrary, the fistula tends to enlarge. Various means to overcome this difficulty, some operative, some mechanical, have been recommended, but none seems to have attained the desired end.

Girard, before the local Medico-Pharmaceutical Society of Berne, on May 1st, described an operative procedure which he had applied several weeks before in the case of a patient in the hospital. The patient, unfortunately, only consented to the operation after he had been much reduced by inanition, and only survived the operation one day; and died of debility.

A vertical incision, about six inches long, was made, dividing the upper portion of the left rectus abdominalis. The abdominal cavity was opened at the middle of this incision, a conical portion of the anterior wall of the stomach in the neighborhood of the fundus drawn out, and the base of the cone, by means of silk sutures, accurately attached to the margins of the abdominal incision—that is, the peritoneum and the posterior layer of the sheath of the rectus muscle. Then a finger's breadth of muscular tissue, on each side of the incision, was separated, preserving about four inches, and these two bridges of tissue so looped over one another, in a measure crossed, that a muscular sphincter was formed, through the opening of which the apex of the cone of gastric wall was brought out. A number of catgut sutures fixed the muscular masses and the gastric cone in position. On account of the feebleness of the patient, it became necessary at once to open the stomach with a puncture and inject liquid nourishment through a drainage tube of small calibre.

It was hoped that by this device the sphincter made in the voluntary muscular tissue could be closed voluntarily by contraction of the rectus muscle, and, at any rate, that its enlargement would not occur. Even though the bridges of muscular tissue should undergo fibrous degeneration, on account of their connection with the rest of the muscle, above and below, they would act as sphincters by its passive extension.

The post-mortem examination showed that everything had remained in its proper position; the stomach was already firmly adherent to the peritoneal opening.—*Correspondenz Blatt*, June 1, 1888,

Sulphonal.—Dr. Salgo, in the *Wiener medizin. Wochenschr.*, No. 22, reports upon the use of sulphonal in a few cases, at the Insane Asylum at Budapest. The drug has not proven efficient in all cases, as in the sleepless, restless paralytics; but it was of service in some, as in a case of severe virile hysteria, in hypochondriasis, in epilepsy and others. The sleep caused by sulphonal was longer and calmer that that from paraldehyde. On account of its tastelessness, sulphonal was better taken than paraldehyde or chloral.—*Münchener medizin. Wochenschr.*, June 5, 1888.

Phenacetin.—Rumpf, of Bonn, in the *Berlin. klin. Wochenschr.* of June 4, 1888, formulates the following conclusions as to the action of phenacetin:

1. Phenacetin is a certain antipyretic, free from unpleasant effects, which may be given in doses of seven and a half grains to adults, and of three to four grains to children.

2. Phenacetin can be administered as an antineuralgic, in doses of fifteen grains:

a. In all cases of vaso-motor neuroses.

b. For the lancinating pains of tabes and the neuralgias of chronic neuritis.

c. As a palliative remedy in the most various neuralgias.

Bloodletting in Diseases of the Eye.—Fieuzal (*Archives d'Ophthalmologie*) states that local and general bloodletting has unjustly been almost forgotten. Particularly in diseases of the eye may bleeding be followed by excellent results. The writer has thus successfully treated cases of retino-choroiditis, simple choroiditis and sclero-choroiditis. Frequent bleeding may also be applied in cases of neuritis and cyclitic processes after operations for cataract. Local bleeding is better done with the heurteloup than with leeches, because the latter do not act rapidly enough. After the bleeding the eye must be bandaged and kept in a dark room for twenty-four hours, so that an increased supply of blood to the choroid is prevented.—*Memorabilien*, May 31, 1888.

Physiological Action of Cocaine.—This has been studied by Mosso (*Annal. de Pharm. et Chim.*) experimentally, who finds cocaine to be our best cerebro-spinal excitant. If an animal has taken a deadly dose of chloral hydrate and is in a deep sleep or comatose condition, an injection, hypodermatically, of one-eighth to one-sixth of a grain of cocaine to each 2.2 lbs. of body-weight suffices to increase the frequency of the pulse and to bring about an awakening of the animal, but the low temperature produced by the chloral remains the same. On the other hand, three-quarters of a grain of cocaine will counteract the effects of twenty-three grains of chloral hydrate. Under these circumstances Mosso believes that cocaine may be advantageously administered in cases of poisoning by chloral hydrate, opium, morphine and other narcotics which bring about a sedative action on the nerves and circulation and respiration.—*Pharmaceutical Record*, June 15, 1888.

A New Surgical Soap.—In the *Revue Médicale de la Suisse Romande*, No. 5, 1888, page 285, Prof. Auguste Reverdin, of Geneva, speaks highly of a "surgical soap" prepared after the following formula:

R.—Oil of sweet almonds . .	72 parts.
Lye (*lessive*) of soda . . .	24 "
Lye of potash	12 "
Sulpho-carbolate of zinc . .	2 "
Essential oil of roses . .	9.5 "

(Mem.—The preparation consists in slowly adding to and carefully mixing with the almond oil the lyes and the sulpho-carbolate, part by part until an intimate and homogeneous mixture is obtained.) The latter is kept for several days at 68° F. The mass, which gradually acquires the consistence of soft paste, is then divided into any number of portions that may be desired; these are placed in suitable moulds, in which they are kept till they are completely solidified.

Prof. Reverdin has been using this antiseptic soap

since the summer of 1887, when he visited Prof. Bottini's clinic at Milan, where it is extensively employed for various purposes. The soap is said to possess wonderful cleansing, as well as antiseptic, properties, and it does not irritate the skin, however sensitive or irritable the latter may be. Moreover, as the soap contains an excessive proportion of fatty substances, it does not dry the skin. The presence of potash makes the soap by far more active comparatively than a pure sodic soap, since, as Dr. Unna has proved, potash has a more energetic solvent action on the horny layer of the cuticle than soda.

Prof. Reverdin recommends this soap not only for general use in hospital and private practice, but also for washing the hands in dissecting-rooms and everywhere where the hands come in contact with decomposing substances. Further, he urges that barbers should universally adopt this disinfecting soap for their purposes, and thus protect their customers from various infectious diseases, to which they are exposed in their shops. Prof. Reverdin has also obtained good results from this soap in various cutaneous affections. Finally, it is a very pleasant toilette soap, as he himself and many of his patients and friends have found. — *British Medical Journal*, June 30, 1888.

The Treatment of Certain Forms of Dyspnœa with Carbonic Acid Gas.—Edm. Weill, before the Paris Académie des Sciences, in February, stated that he had successfully treated the dyspnœa of pulmonary and laryngeal phthisis, and of emphysema, by the inhalation, twice daily, for two to five minutes, of a half to a gallon of carbonic acid gas. In a recent paper, René Chabannes, of Lyons, confirms the foregoing. He has used the inhalations for the dyspnœa of advanced pulmonary and laryngeal tuberculosis, in asthma, in catarrhal affections, as well as in cardiac and renal disease, and is satisfied with the results. The technique is simple: 4 drachms of bicarbonate of sodium and 3 of tartaric acid, producing a gallon or more of carbonic acid, are placed in a flask with a caoutchouc stopper perforated by an angulated glass tube, through which the gas is inhaled; or the patient may mix the materials in a glass and inhale the gas as it is developed.—*Wiener medizin. Pr.*, June 10, 1888.

Creolin—a New Antiseptic.—Amon (*München. medizin. Wochenschr.*, June 26, 1888) has had good results from the use of creolin in scrofulous and phlyctenular conjunctivitis and keratitis, in diphtheria and in pulmonary tuberculosis. He uses solutions of one-quarter to two per cent., applied locally and inhaled. The drug is said to be non-toxic, cheap and efficient as a germicide. These are the author's conclusions in reference to its use in pulmonary affections:

It is inhaled readily and without deleterious result.

The inhalations facilitate expectoration, cause a diminution in the secretion and afford the patient relief.

Fetor of the expectoration is overcome or diminished. A three per cent. creolin powder is advantageously added to the spit cups.

In some cases in which the infiltration involves only the apices or small areas of an upper lobe, good results follow (disappearance of rales and clearing up of dulness).

A New Artificial Fluid for Counting Blood Corpuscles.—At the last session of the Paris Académie des Sciences, Mayet submitted a new artificial fluid for measuring the corpuscular elements of the blood. Four cu.mm. (6½ minims) of blood are mixed with 500 cu.mm. (1⅔ fluid ounces) of a watery solution of osmic acid, and allowed to stand for three minutes. Then 500 cu.mm. (1⅔ fluid ounces) of a mixture of 45 cu.cm. (1½ fluid ounces) of pure glycerin, an equal quantity of distilled water and 17 cu.cm. (4⅔ drachms) of a watery solution of eosin are added. The red corpuscles are colored red by this solution, while the white remain uncolored. By this means the counting is notably facilitated.—*Wiener medizin. Pr.*, June 10, 1888.

Local Anæsthesia.—Liebreich, in experiments on rabbits and guinea-pigs, by means of injections into the pleura or instillations into the eye, found that local anæsthesia was produced by ammonium chloride, but not by the carbonate or nitrate; the iron salts are also anæsthetic, especially the sesquichloride; also the acetate of lead, but not the zinc salts. Of organic substances, hydrochinon, resorcin, antipyrin; of the oils, turpentine and eucalyptol are local anæsthetics. These medicaments paralyze the terminal nerve filaments and irritate the portions immediately adjacent. They probably exert a caustic action, cause vascular dilatation and a condition which has been called anæsthesia dolorosa. The duration of the anæsthesia is variable. In the case of the chloride of iron it was two hours and more.—*Transactions of the Seventh Congress für Innere Medicin.*

Rheumatismus Nodosus.—Lindmann, of Manheim, in the *Deutsche medizin. Wochenschr.*, June 28, calls attention to the development of subcutaneous nodules in cases of acute rheumatism, "rheumatismus nodosus." They occur mostly in the young and in females, at about the third week of the disease, in numbers from one to more than fifty, in size from a pin's-head to an almond, their favorite seat being at the knee and elbow-joints, over the extensor tendons on the dorsum of the hand, at the malleoli and at the spinous processes of the vertebra, on the occiput and forehead, though there is no part of the body where they may not be.

The author comes to these conclusions:

1. In articular rheumatism, particularly in youth, subcutaneous nodules at times occur as a symptom.

2. Very frequently a cardiac affection, at times with chorea, exists at the same time.

3. They are sometimes the only symptom of the existing rheumatic affection; there is, at times, an exacerbation of the cardiac affection with their appearance.

4. They demand no therapeutic interference.

The Alkalinity of the Blood in Disease.—From a study of eighty-eight cases, v. Jaksch (*Zeitschr. f. klin. Medizin.*, xiii. 3 and 4) arrives at the following conclusions:

1. Fever mostly leads to a more or less marked diminution of the alkalinity of the blood. 2. This is a constant feature in uræmia. 3. Diseases of the liver, with destruction of tissue, give rise to the same symptom. 4. Leukæmia, pernicious anæmia and chlorosis scarcely cause any alteration of the alkalinity. 5. CO poisoning also seems to diminish the alkalinity.—*Fortschritte der Medizin*, June 15, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

THE HYGIENIC TREATMENT OF SMALLPOX.

DURING the season just ending smallpox has, as usual, figured largely in the death-rates of most large cities. In some, especially in Europe and South America, the disease assumed formidable proportions. In this city the number was not large enough to entitle it to the name of an epidemic. Through the courtesy of the Health Officer we learn that since the first case was reported, in the middle of March, there have been slightly more than two hundred cases, with a death-rate of not quite twenty-five per cent.—an average mortality. Yet the occurrence of even this number of cases shows with what tenacity the disease hangs on, and indicates the necessity of the most vigorous means in controlling it.

Smallpox is unique among human diseases in having an almost perfect prophylaxis; but ignorance and indifference prevent its complete application. Compulsory vaccination, as practised in Germany, would probably be objected to in this country, as an infringement of personal liberty, and as vaccination itself does not protect in every case, there will probably always be enough predisposed persons to keep up the source of the disease. The possibility of extirpating smallpox must, therefore, be given up as visionary, and every effort that the means in our power will permit devoted to rendering it impotent. These means are, beside vaccination, isolation and disinfection.

Isolation, to be perfect, must be carried out in separate wards or barracks. To undertake this in rooms in large hospitals is difficult and dangerous. Under all circumstances, however, disinfection of the patient, the room, in short, of everything falling under suspicion of infection, must be practised. Ignorance of the cause of a disease is not, as has been alleged, any hindrance to disinfection. In the case of smallpox we may assume that the cause is a living organism, so that the general rules of antisepsis are applicable here as to other contagious diseases. The necessity for disinfecting the skin lesions is evident, since they must contain the contagious principles. Smallpox is probably not contagious during the earlier stages, but from the duration of the crusts, the length of certain epidemics may be understood. Thus some cases must remain sources of infection for five or six weeks.

To disinfect the face, and by this also limit the suppuration and consequent disfigurement, applications having undoubted antiseptic properties should be used. The occasional use of solutions of corrosive sublimate of the strength of one to one thousand, or of thymol one to thirty, will be found efficient and safe. For the rest of the body baths are means not only of disinfection, but also of giving the patients a great deal of relief. Warm water loosens the crusts and greatly diminishes the inflammation which accompanies the exanthem and which sometimes lasts so long. Baths should, therefore, be given daily, in water at the temperature of the body, and lasting from one-half to one hour. Various antiseptics have been proposed as adjuvants to the baths. Many of them are excluded by the danger of poisoning. In a recent number of the *Lyon Médical* the use of soft soap is advocated. This has undoubted germicidal powers, arresting the growth of anthrax bacilli, or in stronger solutions (1 to 1000) killing them. It is not, however, equally fatal to some other bacteria, such as those of putrefaction. Half a pound of soft soap, in a bath of fifty to sixty gallons of water, could be used with safety, though the physician should observe carefully its action on the skin, some persons being very sensitive to its effects.

Bed linen and other infected articles of clothing are best disinfected by exposing them to the action of vapor of water at or above the boiling point for a period of one-half to one hour, according to the size of the object. When the proper heating apparatus cannot be had, repeated boiling will probably give results as trustworthy. Furniture should be washed with strong solutions of bichloride of mercury and then with soap and water.

The greatest difficulty will often be encountered in disinfecting rooms. Heat is out of the question. Sulphur and chlorine vapors were formerly used extensively, but beside being inapplicable to many rooms, are uncertain at the best, and now given up. The plan originated by Guttmann, of spraying the rooms with bichloride solutions, has many disadvantages, and is not within the reach of all. The Berlin police authorities have recently rejected all these methods, and adopted one long known, and shown by experiments of Esmarch to be certain. This consists in rubbing down the walls and other surfaces with bread, the immediate burning of the latter, of course, following.

The indications here given seem to be at present the best, indeed the necessary, means of controlling what has ever been looked on as one of the greatest scourges of the human race, and only by carrying them out with exactness can we hope to keep it within the smallest possible limits.

SACCHARIN.

Through the daily papers we learn that saccharin is to be made the subject of a parliamentary investigation in France. Increased consumption of it has so reduced the price that it has seriously interfered with the beet-sugar industry. In this country it has apparently not received so much attention as in France and Germany.

According to Paul Cheron (*L'Union Médicale*, No. 81, 1888), the saccharin of Fahlberg is not the only substance which goes by that name. Péligot has applied it to a hydrocarbon of no present importance. Fahlberg's saccharin, derived from coal-tar, is an acid anhydro-ortho-sulphamido-benzol, capable of combining with bases. It appears as a white, crystalline powder. Its solubility varies with its purity, but as made by Fahlberg it dissolves in two hundred and eighty-six volumes of water at 50° F., and in eleven volumes at the boiling-point. It is slightly more soluble in alcohol and ether. The addition of alkaline carbonates increases its solubility. It is eliminated unaltered in the urine. The milk and the saliva do not contain it. It has no effect on nutrition or on the elimination of nitrogen. It is equal in sweetness to two hundred and eighty times its weight of sugar, and the sweet taste may be perceived in a dilution of one to seventy thousand. It is this property on which is based its employment in diabetes, and the question as to its harmlessness or the reverse is, therefore, of great importance and must be studied with care.

Stutzer, Abeles, Pollatschek and Mercier regard it as harmless, even when taken for a long period, and this opinion is shared by Adduco and Mosso. On the other hand, many see in saccharin grave disadvantages. Worms has given it in doses of one and a half grains daily in diabetes: one patient supported it well, three others were compelled to stop at the end of a fortnight. Loss of appetite and epigastric uneasiness were the chief symptoms.

Hedley has noted the rapid development of a very disagreeable, sweet taste: Kohlschutter and Elsasser have observed in their cases diminution of polyuria and of sugar, but with loss of appetite. Dujardin-Beaumetz believes that the stomach and intestinal symptoms are due to the action of saccharin on the ferments of the alimentary canal. Stutzer has shown that in artificial digestion saccharin does not hinder the action of the gastric juice, and Salkowski found albuminoid digestion unimpaired in its presence. The latter found, also, that it interferes with the saccharifying action of the saliva and pancreatic juice in an acid medium, but that when neutralized the conversion proceeds.

It is, therefore, evident that in some cases saccharin is badly supported. Probably the renal condition and impurities in the drug have something to do with the result; certain it is that it will often not be tolerated. It has been claimed that through its action on fermentative processes saccharin would prevent the formation of boils and carbuncles, but this is only a hypothetical advantage, and it is only too evident that in diabetes nothing must be done to compromise the digestive apparatus. Our present knowledge, then, goes to show that saccharin is to be given, if at all, with great caution.

Saccharin is, to a certain degree, antifermentative and antiseptic. Macnaughton Jones believes it equal to salicylic acid and thymol. In the diabetic it inhibits the torula fermentation and thus might be used in cystitis. In tuberculous cystitis it has failed, but it has been used with success in simple cystitis with ammoniacal fermentation. As a microbicide of some power, saccharin has been proposed as an intestinal antiseptic, but the necessity of employing small doses and the danger of creating digestive trouble must render such use rarely indicated.

In pharmacy, saccharin has been used to disguise the taste of very bitter medicines, such as quinia. Lutz has advised for that purpose two solutions, one

a strong alcoholic solution, the other a combination with mannite. These vehicles are to be so dosed that fifteen grains of the preparation equal one hundred and fifty of sugar or two hundred and twenty-five of simple syrup. It has also been suggested as a preservative for mixtures. For all these purposes, however, there is the same risk, in prolonged use, of exciting digestive disturbances.

The French health office has expressed the opinion that saccharin cannot be indiscriminately taken in large quantities, particularly as a substitute for sugar, regardless of health, and the Minister of Agriculture has issued a decree forbidding its importation. At the same time the use of the drug in the preparation of confections and syrups is also forbidden.

The next International Congress of Otology will be held at Brussels, from September 10th to 16th, Dr. C. Delstanche being president-elect. American otologists who desire to be present are invited to address the Secretary, Dr. C. Goris, 143 Rue Royale, Brussels.

At their late annual meetings, Dr. Charles N. Lewis, of Jackson, was elected President of the Michigan State Medical Society, and Dr. P. S. Conner, of Cincinnati, President of the Ohio State Medical Society.

The Eighth Annual Meeting of the Lehigh Valley Medical Association will be held at Paxinosa Inn, near Easton, Pa., on Wednesday, August 15th. The annual address will be delivered by Dr. Thomas J. Mays, of Philadelphia, who has chosen for his subject "The Treatment of Lung Cavities."

The Southern Surgical and Gynecological Association will hold its first meeting at Birmingham, Alabama, on the 11th, 12th and 13th of September, 1888. Dr. W. D. Haggard, of Nashville, Tenn., is the President.

At the meeting of the Examining Board of the U. S. Marine-Hospital Service, recently convened in Washington, twenty-one candidates presented themselves. Of these, four were rejected on account of physical disability, three withdrew, and six made the necessary percentage to pass.

In the Quarterly Report of the Secretary of the Illinois State Board of Health, presented to the Board on June 29th, Dr. Rauch, in announcing the adoption of a three years' course by the Jefferson Medical College of Philadelphia, and the College of Physicians and Surgeons of New York, stated that "intimations have been received from other colleges that they will soon do likewise."

A remarkable sequence of multiple births, reported from Henry County, Georgia, is worth remembering when the subject of the unfruitfulness of American women is brought forward for discussion. Mrs. B., aged twenty-six years, was married a little more than eight years ago. During that eight years she has had five confinements and has given birth to eleven children. At no birth were less than two children born; at the second, triplets were delivered, while at all the others there were twins. The children all survive, the youngest being four months old. The account from which the above is taken does not state whether the heroine is white or colored, but, from the context, we infer that she is white.

The Medical Chamber of the Province of Hanover, at its session of May 8th, discussed secret proprietary medicines and means for their suppression. The fact that proprietary medication had grown to a degree dangerous to the public welfare, and that legislation restraining it was a pressing necessity was acknowledged by the majority, independently of appeals to the government meanwhile, as a proper regulation of this matter was anticipated.

Dr. A. Y. P. Garnett, of Washington, died at Rehoboth Beach, Delaware, on Wednesday night, July 11th, of heart-failure. He had been severely ill for several days, and was believed to be slowly convalescing. He left Washington for the seashore on the morning of his death, for the purpose of recruiting his failing health.

He was born in Virginia, in 1820, was graduated in medicine at the University of Pennsylvania in 1841, entered the United States Navy as Assistant Surgeon the same year, was promoted to Surgeon in 1848, and resigned in 1850, in order to accept the Professorship of Clinical Medicine in the National Medical College of Washington. At the breaking out of the war he left Washington and attached himself to the medical staff of the Confederate Army. At the close of the war he returned to Washington, and was again elected a Professor in the National Medical College. In 1887 he was elected President of the American Medical Association, and presided at the late meeting in Cincinnati.

REVIEWS.

THE PHYSICIAN'S LEISURE LIBRARY. Nos. 8 and 9. THE INFECTIOUS DISEASES. By CARL LIEBERMEISTER. Translated by E. P. HURD, M.D. George S. Davis, Publisher, 1887.

UNDER the subject of infectious diseases one naturally expects to have considered more than some of the acute exanthemata, malaria, typhoid fever and diphtheria, yet that is all we can find in the volumes forming the subject of this notice. In addition to the sin of omission, the diseases mentioned are by no means adequately described. The chapters on etiology are not up to our present knowledge, notably as regards malaria and typhoid, and the therapeutic notes, in the form of extracts from journal articles, present nothing new. What useful purpose these volumes can serve is difficult to conceive, since they do not represent the author, and fall short of the purposes of a compend, which latter both form and price seem to suggest.

THE ESSENTIALS OF MEDICAL CHEMISTRY AND URINALYSIS. By SAMUEL E. WOODY, A.M., M.D., Professor of Chemistry and Public Hygiene, and Clinical Lecturer on Diseases of Children, in the Kentucky School of Medicine. Second Edition. Revised and Enlarged, with eighty-five illustrations. Louisville: John P. Morton & Co., 1888.

The title of this little work indicates its scope, and it is remarkable how much the author has compressed into such a small space. The greater part is devoted to an outline of inorganic and organic chemistry, and might be read with profit by many who no longer hear lectures. The section on the urine, having only twenty-one pages allotted to it, has necessarily been very superficially treated, though, so far as it goes, the statements made and directions given are fairly reliable.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, June 4, 1888.

THE VICE-PRESIDENT, S. W. GROSS, M.D., IN THE CHAIR.

DR. J. HENRY C. SIMES read a paper on

THE INJECTION OF A SOLUTION OF COCAINE INTO THE URETHRA FOLLOWED BY DEATH.

(See page 70.)

DR. SIMES then reported a case of

TRAUMATIC ANEURISM OF THE VERTEBRAL ARTERY, THE RESULT OF A GUNSHOT WOUND.

Eliza S., forty-one years of age, was admitted to the surgical ward of the Episcopal Hospital on November 13, 1887. The history given was that on November 9th, four days previously, she had been accidentally shot in the neck. Her condition when admitted was as follows: On the left side of the neck, directly over the line of the carotid artery, about its middle, was seen the wound of entrance of the ball; just above this wound were two small abrasions of the skin. Over the whole anterior part of the neck, and extending two or three inches over the thorax, there was seen an ecchymosis of a greenish-yellow color. At the seat of the wound, covering an area of about two inches, was observed a swelling, not very decided. Upon palpation, this swelling pulsated markedly, and was undoubtedly expansile in character; also of an extremely vibrating nature, feeling very much as if the fingers were in contact with a galvanic battery; upon auscultation, a distinct thrill and loud bruit were quite manifest. There were swelling, pain, especially on movement, and some slight paralysis of the left arm. The general condition of the patient was fairly good.

On November 15th, two days after admission to the hospital, at a consultation of the surgical staff, it was decided to attempt to ligate the common carotid artery, believing it, or one of its branches, was injured. During the interval of two days, the swelling had increased in size, and the thrill and bruit had become much more distinct; the ecchymosis had also extended further over the thorax. Ether was administered, and a ligature was passed around the common carotid artery, just above the clavicle. Pressure upon this artery, while lessening the pulsation of the tumor, did not, however, perfectly stop it. Before tying the ligature, which had been passed around the carotid artery, the operator continued his incision upward over the swelling, and threw a ligature around the artery above it. The ligature below was now tied, and instantly a most terrific flow of blood gushed out of the wound. The upper ligature was immediately tied, but had no control over the hemorrhages; artery forceps and fingers were employed to seize any and all bleeding points, but the blood continued to flow; finally, Dr. Nancrede thrust his finger deep into the wound, against the vertebræ, when the hemorrhage at once stopped.

It was now evident that the vertebral artery had given away; indeed, the fractured vertebra was felt at the point whence the bleeding came. The possibility of ligating the ruptured artery could not, under the circumstances, be entertained; it was not practicable, and the only procedure which suggested itself as possible, was to plug the artery in the foramen through which it passes. A piece of cork was cut of suitable size, and an attempt was made to insert it into the long canal; this, however, was not successful. A long strip of lint, one inch wide, was now, by means of the fingers and forceps, forced into the canal, and the hemorrhage ceased; the wound was packed with lint, and over it a shot-bag was placed, to act as a compress.

The patient was considerably shocked, but under suitable treatment soon reacted. It was thought best not to remove her from the operating-table; by the use of sandbags the head was made immovable, and she was cautioned as to the danger of bleeding by making any effort on her part to move.

The result was in great part due to the woman herself; she proved to be a most willing and obedient patient. Morphia was ordered to allay restlessness, with milk and beef-essence for food. On November 16th, the next day, she was doing well, temperature normal, pulse good, no difficulty in taking her nourishment, and she had slept fairly under small doses of morphia. On the next day she was removed from the operating-table to a bed without difficulty. *18th.* No change, except elevation of temperature, 101°, undoubtedly occasioned by beginning

of suppuration in the wound. *19th.* The wound freely suppurating; removed some of the packing, washed with bichloride of mercury solution, and dusted with iodoform; temperature to-day 102½°. *20th.* Removed more of the lint packing, and employed same dressing; temperature 101½°. *21st.* The wound looks very well and granulating; removed more of the lint; temperature 102°. *22d.* The last of the lint was removed, and the wound was seen to be contracting very fast. From this date until November 29th, there did not arise any unfavorable symptom, the patient continued to improve in general health, and the wound in the neck all healed, with the exception of skinning over at one angle. At this time there were first noticed some cerebral symptoms, which very rapidly increased; there were ptosis of the left eyelid, and hemiplegia of left side; she soon became unconscious, and died on Dec. 2d.

The *post-mortem* showed softening of the entire right side of the brain. An examination of the neck disclosed the left carotid artery from its origin at the aorta to be obliterated by a thrombus. The vertebral artery, where it passes through the foramen in the fifth vertebra, was destroyed, and about half an inch of its continuity was missing; the remaining portion was filled with a thrombus. There was a comminuted fracture of the transverse process of the fifth vertebra, and the pistol-ball was found lying against the body of this bone. The spinal canal was not opened, nor was there any apparent lesion of the cord or its membranes.

Dr. Charles B. Nancrede said that the thrill which was present in this case presented certain peculiarities. Before the operation was commenced, he expressed the opinion, based on the sound, that it was either an arteriovenous aneurism in which the internal jugular was involved, or else more than one vessel was involved. After placing the ligature around the common carotid, and while trying to pass the aneurism needle around the distal part of the vessel, it entered something from which arterial blood oozed. After failing to check it with forceps the lower ligature was tightened. Pressure on the vessel below had before caused a marked diminution of the pulsation in the swelling. The moment that the ligature was tightened, there was a most appalling gush of blood. The pressure forceps caught a mass of tissue in the upper part of the wound from which blood was flowing. The blood, however, continued to gush out. He then placed the fingers of both hands into the wound, tore it open, and gripped the tissues outward, without any effect. He then made pressure inward. This also failing, he pressed backward, and his thumb slipped into the opening in the vertebra. He believed that several vessels were involved; the distal end of the carotid, the jugular vein and the vertebral artery were bleeding at the same time. He did not think that the vertebral alone could have poured out this large stream of blood.

One point of interest was the effect of the application of Esmarch bandages to the limbs, with elevation, in the almost fatal syncope which followed the bleeding. He could not help thinking that the repeated hypodermatic injections of a saline solution were of decided benefit.

Dr. S. W. Gross said that unquestionably the first case recorded of antiseptic plugging of a wound to arrest arterial hemorrhage, was that of a stab-wound of the neck, in which the vertebral artery was involved. The wound was plugged with iodoform gauze, the bleeding checked and the patient recovered. The operation was performed by a German surgeon.

Dr. Ferdinand H. Gross reported a case of

GUTTA ROSACEA

(or what, in the classification of some writers on dermatology, is termed acne rosacea), and showed a number of photographs representing the patient as he appeared before and after a successful plastic operation had been performed for the relief of the disfigurement of the nose. The unsightly protuberance arose and continued to increase in size during the third stage of the disease, when, with greater expressiveness, the malady is called Rosacea Hypertrophica.

The patient, a carpenter by occupation, was in his fifty-seventh year, and had been affected with rosacea for at least twelve years; while the third stage had endured for about one-fourth of that time. He was never afflicted with specific disease or any other malady of importance, except dyspepsia. He was not a free drinker; although not totally abstemious in the use of liquors, his complaint could not be ascribed to intemperance. When Dr. Gross was first consulted in the case, numerous medicaments had already been administered internally, and local applications had been ineffectually tried. The patient had become sullen and taciturn, refusing to mingle with his usual associates, or to continue his ordinary vocation. His digestive apparatus was out of order, and the dyspeptic condition, already alluded to, was doubtless a factor in the disease, and needed correction. The protuberances seen upon the tip and ala of the nose, obstructed the left nostril, and rendered breathing labored and difficult. The peculiar unevenness and craggy appearance of the affected skin were well marked.

In addition to the earlier changes of the disease, such as passive congestion and dilated bloodvessels, rosacea in the later form here presented consists essentially of hypertrophy of the connective tissue, when the nose may attain enormous proportions; but this condition is rare, and is looked upon by some writers as a dermatological curiosity.

Attention was directed to the disturbed digestive functions before the knife was used to reduce the enlarged and lobulated nose to normal proportions. This was done by first carrying an incision along the lower free border of both alæ (the edge of the knife being directed upward), and the line of the cut passing through the lobe just above the anterior limit of the columna, and through the lumpy masses at that point and on the left ala. To this long incision was joined another, running vertically on the dorsum of the nose from bridge to tip. Two triangular flaps of the thickened integument of the wings of the organ were next dissected up, and the superabundant cellular tissue and lumpy projections were trimmed and scraped away. While doing this, any injury to the lower lateral cartilages was avoided. Hemorrhage was rather copious, as might be expected from a part so congested, but the free bleeding had its beneficial effect upon the final favorable result.

The disease never becomes malignant in its nature, though it may sometimes return. It is now nine months since the operation was performed, and there are no evidences of further trouble. The result of the operation was entirely satisfactory. The nose now presents a normal and shapely appearance, and the photograph recently taken shows no scars.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, June 22, 1888.

FIRST VICE-PRESIDENT, WILLIAM GARDNER, M.D., IN THE CHAIR.

DR. LAFLEUR presented the specimens obtained from a case of

MULTIPLE CAPILLARY HEMORRHAGE AND FATTY DEGENERATION OF THE PANCREAS.

The patient was a man, aged fifty, who had been under the care of Dr. Ross. For several years he had suffered from obscure dyspeptic symptoms. Twenty-four hours before death he was seized with a severe pain in the epigastrium and vomiting; he became collapsed, and rapidly sank. At the autopsy the pancreas was found to be uniformly enlarged to more than twice its natural size, of a dark-reddish color, externally; on section, firm and of an almost uniform, dark-red hue, mottled here and there by grayish patches which resembled the normal parenchyma of the organ. A thin section showed that the general, dark color was due to numerous close-set capillary hemorrhages, separated from one another by a grayish, translucent material. Microscopic examination confirmed the nature of the changes; the hemorrhagic portions having a brownish-red color and presenting a peculiar fissured appearance (due probably to freezing the specimen in making the section). In addition there was universal fatty degeneration of the tubules and acini. The cellular tissue around the pancreas was blood-stained. There was no peritonitis and no evidence of disease in any of the organs.

DR. WILLIAM GARDNER reported a case of

EXTIRPATION OF THE UTERUS BY THE VAGINAL METHOD,

for malignant disease. The case presented several features of unusual interest. The patient, who was unmarried and aged forty-three, had suffered for seven years from pelvic pain, uterine hemorrhage and other discharges; at times fetid, fleshy masses were expelled from the uterus. Anæmia and cachexia were marked. On examination under ether, the uterus was found uniformly enlarged—five to six inches in depth—the cavity much enlarged, and the lining membrane nodular and roughened; extirpation was recommended, and, after due consideration, the patient consented.

Dr. Gardner expected unusual difficulty in the operation because of the large uterus and narrow, rigid vagina and perineum. After ligature of the bases of the broad ligaments and separation of the uterus in front and behind, the uterus was reduced in size by excision of portions. In this way the organ was removed *per vaginam* without much difficulty. Dr. Gardner said he had contemplated the possible necessity or feasibility of a combined vaginal and abdominal operation; detaching the uterus from above after abdominal section, and completing the separation from below, finally lifting the uterus from the pelvis through the abdominal incision. This, however, proved to be unnecessary. Although the operation was a very severe one in the weak state of the patient, she was in a remarkably good condition when put to bed, but she died of peritonitis in forty-eight hours.

Dr. Gardner said that this was the first death he had had in this operation. He had removed the uterus six times by the vaginal method. The present fatal case was by a great deal the most difficult of all. The specimen showed great thickening of the walls of the uterus. Microscopical examination by Dr. LaFleur showed the disease to be a malignant adenoma. The thickened walls were composed of apparently healthy, smooth muscle-fibres, an hypertrophy, probably the result of long continued irritant influence of the disease on the endometrium.

DR. TRENHOLME congratulated Dr. Gardner on his great success in extirpation of the uterus by the vaginal method; a mortality of one in six was a good record. He had himself extirpated the uterus ten times with recovery in only four cases. In some of the cases in which he had operated the condition was desperate and there was but slight hope of recovery from the first. He was very doubtful of the advisability of extirpation of the uterus for malignant disease, and he had almost given up performing the operation. In the specimen presented by Dr. Gardner it appeared to him that the case was non-malignant, the uterus was not fixed and the growth did not infiltrate. In such a case he thought a thorough curetting of the uterus and the application of electricity by Apostoli's method would have been more suitable than excision.

Dr. Trenholme preferred the abdominal operation in removing the uterus; he made use of the V-shaped incision according to the method introduced by himself. This method of making a flap of the cervix was suitable to cases of myomata and was better than ligature by wire, etc. The two flaps formed by the V-shaped incision should be sewed firmly together with silk or shoemaker's thread, and in this way the cavity was completely closed and the danger of hemorrhage prevented. Should drainage be necessary, a tube could be passed through the centre of the stump into the vagina. He thought this operation would have been suitable in Dr. Gardner's case, because the cervix was not involved in the disease.

DR. ARMSTRONG said he would have liked to heard more about the combined method. He had no doubt that fetid discharges had escaped into the peritoneal cavity when the uterus was split up. He thought contamination by discharges from the interior of the uterus could have been avoided by the abdominal operation.

DR. GARDNER, in reply, stated he believed the case to be one of malignant disease; clinically it certainly was. His experience with removal of the uterus by abdominal section had not been as favorable as by the vaginal method. In reply to Dr. Armstrong, he said it was quite probable that the peritonitis resulted from the escape, during the operation, of fetid discharges from the uterus.

DR. SHEPHERD read a paper on a case of

EXCISION OF THE TONGUE, FOLLOWED BY DEATH FROM ACUTE MILIARY TUBERCULOSIS.

The patient, a strong, healthy Irishman, aged sixty-four, was admitted into hospital May 19, 1888, suffering from an ulcer on the left side of the tongue.

Patient had never been ill in his life, never had any cough and had been a very moderate smoker. In September, 1887, first noticed a small hard nodule on the left side of the tongue about one inch from the tip. This troubled him and was cauterized by his medical attendant. An ulcer soon formed which increased slowly. On entering hospital his condition was as follows: On the left side

of the tongue, not far from the tip, was an irregular fissured ulcer with undermined, ragged edges and a sloughy base. The whole ulcer was surrounded by a mass of induration, the size of an almond. The ulcer was painful and the patient was unable to masticate his food; not much salivation and no fetor. Some small, hard glands felt in the submaxillary region. Patient's general condition was good and all his organs apparently healthy. Temperature normal. A portion of the ulcer was snipped off and examined, but nothing but epithelial elements found.

From the age of the patient, the history of the case and the appearance of the ulcer with the surrounding induration and involvement of the submaxillary glands, the case was thought to be one of epithelioma, and immediate operation was advised. The operation was performed on May 23d by the method usually employed by Dr. Shepherd in such cases, viz., preliminary ligature of the linguals with removal of the involved glands and excision of the tongue by scissors. The patient recovered well from the operation, and was fed by the rectum for three days. On the fourth day patient sat up and fed himself, but that evening his temperature rose to 101°. Next day he had a pain in his right side and a well-marked friction sound was heard. The wound was perfectly healthy and sweet and granulating well. On the sixth day his temperature rose to 103°, respiration 41 and patient became very weak, and died on the seventh day.

Dr. La Fleur, who performed the autopsy, reported that the wounds in neck and mouth were healthy, without fetor and healing kindly. In the thorax was found a complete adhesive pleuritis of the right side, and also to a lesser extent on the left side. The surface of both lungs was crammed with gray miliary tubercles the size of millet seeds. Left lung on section also contained numerous miliary tubercles. Bronchi normal. Liver and kidney contained a few miliary tubercles, and the right testicle was enlarged and caseous. A microscopic examination of the ulcer on the tongue disclosed numerous tubercles in the floor and around abundant small-celled infiltration. Tubercles found among the muscle fibres.

Dr. Shepherd said there was now no doubt in his mind that the case was one of tuberculous ulcer of the tongue with a latent condition of general tuberculosis, which was lighted up into activity by the operation; he also discussed the difficulties of diagnosticating such cases from epithelioma, especially when the patient was between sixty and seventy years of age. The case was unique in his opinion. Cases of miliary tuberculosis are reported following several weeks after operation, but such a rapid course was very unusual. The immediate cause of death was no doubt pleuritis in a patient already depressed by a severe operation. At the post-mortem there were no evidences of septic infection.

Dr. George Ross said that the surgical points in this case, which had been considered by the reader of the paper, were most important, but the medical questions which were suggested were of far greater interest. He had no doubt that in certain cases the diagnosis between a tuberculous and cancerous ulcer was impossible. The case was interesting, firstly, from the fact of an acute miliary tuberculosis occurring at such an advanced age; such cases were by no means common; still he had seen not a few cases of acute tubercular meningitis in persons over fifty; secondly, the occurrence of acute miliary tuberculosis after operation was new to him. There was no doubt that this affection had come on rapidly, yet it was not in his experience to see acute tuberculosis running such a rapid course. He was inclined to think it was a case of coincidence, and that the affection would have occurred without operation. The focus of infection was no doubt in the tongue or in the testicle. He did not think the tubercle was latent and had been lighted up into activity by the operation, as suggested by Dr. Shepherd; the tubercles were all of the same age and were recent. The patient's temperature, which had been carefully observed for several days before operation, was normal, and an examination of the chest had revealed nothing. The acute pleurisy, no doubt, was the immediate cause of death.

Dr. Bell said he did not believe the operation had lighted up into activity an already existing miliary tuberculosis. How often do we see tuberculous testicles and glands removed and yet no such conditions result. The man may have been in a condition ripe for the development of tuberculosis, and the shock of the operation, or, more likely, the prolonged etherization necessary in such a radical operation as that performed by Dr. Shepherd, may have started the process. In his experience, however, he had never seen acute tuberculosis run such a rapid course. Dr. Bell mentioned a case of acute tuberculosis which had supervened three weeks after an excision of the hip for strumous disease. In this case, however, there was old disease of the lung. In speaking of the microscopic examination previous to operation he said the examination of a superficial portion of an ulcer revealed nothing; a portion of the base of the ulcer should have been excised. He thought tuberculous ulceration of various parts, such as the rectum, bladder, skin, etc., was often overlooked by medical men.

Dr. La Fleur suggested that the rapidity of the disease might be accounted for by the mode of infection, which was probably through the bloodvessels and not the lymphatics. When infection takes place through the blood acute tuberculosis may run a very rapid course.

Dr. Buller reported a case of

Arterio-venous aneurism of the orbit cured by ligature of the common carotid artery.

The patient was a healthy man, aged twenty-eight, who three months before fell from a bridge a considerable distance, striking the right side of his head and fracturing his jaw. The injury was followed by great swelling and pain, and when the swelling subsided the patient noticed that he had double vision. The pain and swelling gradually subsided until two weeks ago, when he noticed that the right eyeball appeared larger than the left and the pain again increased in severity, being so intense as to prevent him from sleeping—pain was throbbing in character, and was increased by pressure. When first seen the eyeball was much protruded, the conjunctiva œdematous and also both eyelids, pupils active, retina œdematous, but no swelling of the optic nerve. Vision of right eye $\frac{20}{C}$. On pressing the eyeball strong pulsation felt. On auscultation a loud rasping murmur heard, synchronous with the pulse. Pressure on the carotid arrests bruit and pulsation, and diminishes size of the swelling. Arterio-venous aneurism was diagnosticated

and ligature of the right common carotid advised. Dr. Shepherd ligated the right common carotid, dividing it between two ligatures. The patient rapidly improved, the proptosis quickly diminished and pain ceased. At the end of ten days the patient had almost normal vision in the right eye and also normal movements. The œdema disappeared and the eye resumed its natural position. The first dressing took place on the tenth day, when the wound was found completely healed by first intention; the bone drain had entirely disappeared. Temperature never arose above the normal.

Dr. Buller promised at some future time to give a more detailed account of the case, and a review of the literature of arterio-venous aneurism of the orbit.

Dr. HINGSTON reported a case of

COMPOUND DISLOCATION OF THE ASTRAGALUS, IN WHICH THE PATIENT REMOVED THE DISLOCATED BONE.

The patient was a man about twenty-five years of age, who fell with his foot twisted under him; on endeavoring to rise he noticed a bone protruding from the region of the ankle-joint. This was loose and he removed it himself with a penknife and brought it to Dr. Hingston. The bone was the astragalus. The patient made an excellent recovery.

NEWS ITEMS.

The Method of Disinfection practised at the Quarantine Station below New Orleans.—No scientific report published by the government this year has been more important than that just made by Dr. J. J. Kinyown, assistant surgeon in the Marine Hospital Service (*Weekly Abstract*, June 29), upon the germicidal powers of the different methods of disinfection practised under the direction of the Louisiana Board of Health at the quarantine station below New Orleans. The report is important, not only because it shows the degree of protection against the importation of infectious diseases through the important port of New Orleans, but also, since the methods of disinfection practised at other quarantine stations are similar to those in use there, the experiments show approximately the efficacy of each mode of disinfection, and suggest changes that should be made in their use.

The three methods of disinfection tested were: the use of bichloride of mercury solution, the application of dry and moist heat and fumigation with sulphur dioxide.

Dr. Kinyown finds the first of these methods defective, because of the difficulty of getting the disinfecting agent into cracks and corners, rubber goods, the under sides of decks, and into lockers, etc. He discovered in all these localities and articles that the microörganisms existing before the disinfection had not been destroyed, and he found them as plentiful on the floor of the forecastle of one ship, that was exceptionally filthy, after it had been drenched with bichloride of mercury for an hour, as before. Dr. Kinyown recommends that, in order to make this mode of disinfection more effectual, the bichloride of mercury be applied with a spray produced by connection with a steam-boiler, and that it be applied after fumigation by sulphur.

The results from the application of dry and moist heat were the most satisfactory of all. Cultivations of various disease-germs exposed to a dry heat of 176° F., and afterward to steam at a temperature of 212° F., were, with few exceptions, destroyed. Dr. Kinyown thinks that, in order to secure absolute protection, the heat should be made greater and the time of exposure increased.

In eleven experiments seventy-four disease-germs were placed in vessels among articles to be disinfected by the use of sulphur dioxide, but only sixteen of the whole were destroyed, or less than twenty-two per cent. Dr. Kinyown has very little to say about this method of alleged disinfection, except to recommend that the sulphurous fumes be applied in large quantities, and be confined in the compartments to be disinfected a longer time. But he reports his experiments in full, and lets them speak for themselves.

The net result of these tests is to show that some disease-germs escape even when the most effectual modes of disinfection practised at quarantine below New Orleans are resorted to, and that less than one-fourth of them are killed when the least effective method is used. We assume that the quarantine and city health officers everywhere will profit by the suggestions of this report, and that the public will be better protected in the future than in the past.—*Science*, July 13, 1888.

A School for Male Nurses.—The New Training School for Male Nurses was formally transferred on July 5th to the City of New York, by Mr. D. O. Mills, through whose liberality the building has been erected on the grounds of Bellevue Hospital. The building is of Carlisle stone and red brick, with terra-cotta trimmings, built in a simple form of the Romanesque order of architecture, five stories and basement in height, in the form of an L, with a frontage of 75 feet on Twenty-sixth street, and 80 feet on the East River. On the main floor are the administration rooms and offices, the dining-room and kitchen, and the matron's and linen rooms. The next four floors are divided into 50 sleeping apartments and closets and bath and toilet rooms, except the two upper floors of the wing overlooking the river. These are thrown into one large hall, about 30 by 80 feet in extent and over 18 feet high, in which will be contained the museum connected with the hospital. The building was furnished completely from top to bottom with white oak chamber and antique oak office, reception and dining-room furniture, linen, bedding, tableware, silver and range furniture, and, as given yesterday to the city, cost the donor nearly $100,000. In presenting the building, Mr. Mills said: "In the great development of means for caring for the helpless sick, which marks the present century, no want has been more felt than that for trained nurses. Medical science has made immense advances, but while the schools furnished physicians, and the humane spirit of the age built and endowed hospitals, it was still hard to supply the skilled care which often does more for the sufferer than medicine. The Training School for Female Nurses was a great gain. Personal observation of the good it has done led me to think that an equal service might be rendered by an institution for the training of male nurses. The humane work of the physicians in charge of Bellevue and other city hospitals could thus be efficiently supplemented, and the sufferings of the poor under their care alleviated, while the community would gladly employ all the male nurses the hospital could spare, and so enable the students thus trained to make the vocation of nursing their life-work. . . . .

I have, therefore, taken great pleasure in erecting for this purpose a building on the grounds of Bellevue Hospital."

The Prevention of Puerperal Fever. — DR. WILLIAM GOODELL writes to the *Medical Standard* (July, 1888), that he succeeded at the Preston Retreat in stamping out puerperal fever from its wards by the following procedure: Previous to the birth of a child, the vagina was cleansed by a quart of (1 to 2000) mercury bichloride solution. After complete delivery the vagina was again cleansed in the same way. A suppository containing twenty grains of iodoform was slipped into the vagina. A pad of sublimated cotton, kept in place by a T-bandage, covered the vulva. His hands and those of his assistant were carefully cleansed by soap, warm water and the nail-brush and dipped into a (1 to 1000) sublimate solution before each examination. After the introduction of this plan into the Retreat, not only did puerperal fever cease to appear, but ophthalmia neonatorum vanished.

Every year, he says, he is called in consultation to see about a dozen women die from puerperal fever whose lives, he is sure, might have been saved had the foregoing treatment been adopted.

Hydrophobia in Paris.—In the first five months of 1888 there were no fewer than 280 applicants at M. Pasteur's laboratory from the Department of the Seine alone, all of whom had been bitten by dogs either known to be rabid or suspected of being so. This number is almost equal to the corresponding total for the whole year 1887, which amounted to 306. The Prefect of Police has, therefore, issued an order that for six weeks no dog shall be allowed to go about the streets of Paris, unless led by a string. The owner of two dogs, which had been in contact with a rabid cur, was recently sent to prison for six days and fined 200 francs ($40) for refusing to have them destroyed. —*British Medical Journal*, June 30, 1888.

The Physician as a Public Man.—The passing away of a man distinguished as physician and citizen is full of suggestion to those who are left behind to uphold the honor of the profession he adorned. The complaint is on many a lip that men are abstaining from their share of the responsibility in public duties. There is not always a clear sense of discrimination between political and public life. The pursuit of politics, as a profession, is not compatible with the diligent performance of other duty, and participation in practical politics is not possible for all men. Neither is public life bounded by the presence of large assemblies or prominent connection with great public enterprises. This country has stretched its civilization and built up its massive structure out of the thought and labor of the common people. The common people means all the people. They who have conceived and directed are one with those who have wrought. With the increase of population is coming, faster and faster, the separating class of those who teach and those who are to be led. The educated man must be the leader wherever he is; the illiterate are always children and seek a leader. In this country the opportunities for public duty are everywhere, from centre to outskirts, and always have there been men from every station to take their part in shaping the civilization. Apart from the pressure of life's necessities, men are everywhere adding to their occupation by confessing their responsibility in the promotion of schemes that look to the comfort and betterment of life for the less favored. There is, through the length and breath of the land, an enormous activity of vigorous life, alert and earnest, though unobtrusive, swaying sentiment and adding to the common fund of improved measures of public weal.

It would be difficult, in this common effort, to compare rightly one man's influence with another's, and it would be unwise to contrast the influence of various institutions, systems or measures. But the persuasive power of the medical profession to influence opinion and mould sentiment is not open to question. It does, however, deserve to be understood. The medical man, educated, sincere and high-minded, who, for two score years working within a limited circle, concentrating the best that is in him on a definite purpose, coming into exceptional personal contact with home intimacies, with an opportunity for impressing his own personality, open to no other calling in life, is a public man, in public life, doing a public service, that cannot be matched for influence on public opinion by any other man in any other vocation, and cannot be overrated. Let any medical man feel that, while this is his possibility, he is one of a vast profession, with common opportunity and common responsibility, and the dignity of his calling in life rises to a plane than which none is higher in the world's activities. The physician is forever in public life, never out of the public eye, and can never be free from the obligations that attach to his opportunities for influence. To have spent such a life well, to have made the years fruitful, not alone in soothing the struggle of the physical life with adverse fortune, but to have taught quietly the lessons of a pure life and an unselfish labor for others, and to have lifted men out of barren thought to exalted aspirations, is a glory for any man. And this crown is within the grasp of any physician. The retrospect of such a life, after its activities are over, cannot fail to be consoling. The profession of medicine may well be proud to hold such lives in fragrant memory.—*Brooklyn Medical Journal*, June, 1888.

Medical Education in Spain.—On May 27th the first stone of the new buildings of the Faculty of Medicine was laid at Barcelona. In addition to liberal accommodation for teaching and original scientific work, they will include a hospital expressly designed for clinical instruction. The site has been given by the town, and the Spanish Government has made a grant of one million dollars for building purposes.—*British Medical Journal*, June 30, 1888.

Dr. Carl Kilcher, assistant at the pathologo-anatomical department of the University at Prague, died recently of blood-poisoning, a result of the inoculation of blood from a typhus fever patient for scientific investigation.

Dr. F. W. Hagen, court physician, and recently professor of psychiatry and director of the mid-Franconian District Insane Asylum, died at Erlangen, at the age of seventy-four.

The University of Utrecht has lost not only Professor Donders, who has just passed his seventieth birthday, but also Professor Koster, who, for more than twenty-five

years, has ably occupied the chair of anatomy. The latter has resigned on account of failing health, and his resignation has been accepted. Dr. Th. W. Engelmann, formerly professor of histology and experimental toxicology, has been elected to the chair of physiology; Dr. C. A. Pekelharing, formerly professor of general pathology and pathological anatomy, to the chair of histology and experimental toxicology; Dr. H. H. Sprouck, formerly lecturer on anatomy, to the chair of general pathology and pathological anatomy; and Dr. E. Rosenberg, formerly professor in ordinary at the University of Dorpat, to the chair of anatomy.

A New Alkaloid in Tea.—At the meeting of the Berlin Physiological Society on June 8th, Professor Kossel reported on a new base, discovered by him, in extract of tea. Caffeine is the only definite chemical base hitherto isolated from tea, and to it are ascribed many of the effects of tea. Professor Kossel has found another base in very small quantity, having the composition $C_7H_8N_4O_2$, upon which he has bestowed the name "theophyllin." It is isomeric with the base obtained from cacao (theobromine), and with paraxanthin obtained from urine by Salomon, but differs from these substances by its reactions. The introduction of a methyl group into theophyllin converted it into caffeine, and as the latter is proved by E. Fischer to be a trimethylxanthin, the former is evidently a dimethylxanthin. Investigations into its physiological effects will be made.—*British Medical Journal*, June 30, 1888.

Narceine. — Laborde and Duquesnel, at a recent meeting of the French Academy of Medicine, reported experiments with this substance, a constituent of opium, first studied by Bernard. A combination known as meco-narceine is most soluble. Narceine is said to be without the unpleasant effects of morphine.—*Revue Gén. de Clin. et de Thér.*, May 10, 1888.

A Medico-legal Case. — The following case of suicide which recently occurred in Jamaica presents features of considerable interest and no little importance. A colored man, after murdering his sweetheart, entered his house, and cut his throat with a razor. Some of the neighbors who had witnessed both deeds rushed into the house, but were unable to find him. After a search, his dead body was found under the house, which was a small one, built on supports, raising it about two feet from the ground. After cutting his throat, the man must have walked or run to the back entrance, a distance of sixteen feet, and then have crept through a hole in the partition, and have crawled on all fours to the spot where his body was found, exactly beneath the room where he cut his throat, and, therefore, a further distance of sixteen feet. The throat was cut from ear to ear by a clean sweep, both carotids and jugulars being severed, as well as the trachea and œsophagus, the wound reaching back to the anterior portions of the bodies of the cervical vertebræ. A blood-stained razor, which was deeply notched, was found in the room, and marks of blood were traced from the room to the back entrance by which the man must have gone out.

Dr. Cargill, who examined the body soon after death, and to whom we are indebted for a report of the case, was asked by the coroner if it was possible for a man to have traversed the thirty-two feet after inflicting such wounds on himself; to which he replied by declining to controvert, as a mere matter of medical opinion, facts that had been sworn to by reliable eye-witnesses. Remarkable instances of the retention of voluntary power after wounds of the carotid artery have been occasionally recorded, but we know of no occasion on which the vessels on both sides of the neck were divided, where so much power was retained by the subject of the injuries as in the present instance. The case should serve as a perpetual warning to medical men not to be too dogmatic as to what is, and what is not, possible even in the presence of the most rapidly fatal wound.—*British Medical Journal*, June 30, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 17 TO JULY 23, 1888.

McPARLIN, THOMAS, *Surgeon* (U. S. Army).—Leave of absence extended one month.—Par. 10, *S. O. 160, Department of the Platte*

WOLVERTON, WILLIAM D., *Surgeon* (U. S. Army).—Leave of absence extended twenty days.—*S. O. 142, Headquarters, Division of the Atlantic.*

DEWITT, CALVIN, *Major and Surgeon* (U. S. Army).—Leave of absence extended one month.—*S. O. 159, A. G. O.*, July 11, 1888.

BANISTER, WILLIAM B., *Lieutenant and Assistant Surgeon.*—Leave of absence extended twenty-seven days.—*S. O. 157, A. G. O.*, July 9, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JULY 14, 1888.

MARTIN, WILLIAM, *Assistant Surgeon.*—Ordered to Marine Rendezvous, San Francisco, Cal., and to attend officers of the Navy and Marine Corps not otherwise provided with medical aid.

AUZAL, E. W., *Assistant Surgeon.*—Detached from duty at the Marine Rendezvous, San Francisco, Cal, and special duty there, and ordered to the Naval Academy.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JULY 16, 1888.

BAILHACHE, P. H., *Surgeon.*—To proceed to Delaware Breakwater Quarantine Station as inspector, July 6, 1888.

FESSENDEN, C. S. D., *Surgeon.*—Leave of absence extended thirty days on account of sickness, July 14, 1888.

PURVIANCE, GEORGE, *Surgeon.*—To proceed to Chattanooga, Tenn., as inspector, July 6, 1888.

SAWTELLE, H. W., *Surgeon.*—Granted leave of absence for twenty-three days, July 9, 1888.

McINTOSH, W. P., *Assistant Surgeon.*—To proceed to Galveston, Texas, for temporary duty, July 14, 1888.

PETTUS, W. J., *Assistant Surgeon.*—Granted leave of absence for thirty days, July 16, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

THE CEREBRAL PALSIES OF CHILDREN.

Clinical Lectures delivered at the Infirmary for Nervous Diseases.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, PHYSICIAN TO THE PHILADELPHIA AND UNIVERSITY HOSPITALS AND TO THE INFIRMARY FOR NERVOUS DISEASES.

LECTURE III.

BILATERAL SPASTIC HEMIPLEGIA.

SYNONYMS.—Spastic rigidity of the newborn (Little). Tonic contraction of extremities. Essential contraction. Spastic rigidity. Permananter Kinder-tetanus (Stromeyer). Spastic paralysis of children (Adams). Spastic diplegia (Gee). Spasme musculaire idiopathique (Delpech).

We have seen that in infantile hemiplegia a great majority of the cases occur within the first three years of life, and in only a limited number is the condition congenital, either the result of intra-uterine disease or of accident during parturition. In bilateral hemiplegia and in paraplegia the reverse holds good; in a large proportion of the cases the trouble dates from birth, and is the result of injury to the child during its passage into the world. Hence the appropriateness of the term birth palsies, applied to these cases by Gowers. Strictly speaking, these cases should be considered together, as they depend on essentially similar conditions, and we may find the arms so slightly affected that it is difficult to say whether the case is one of diplegia or paraplegia; but there is a sufficient number of clearly defined cases in each group to make a division advisable, and there are questions relating to the spastic paraplegia of children which deserve separate consideration.

To the orthopœdic surgeons we owe the greater part of our knowledge of these cases. Heine[1] understood them thoroughly, and to him, I think, belongs the credit of first recognizing their cerebral origin, and separating them from the ordinary infantile paralysis. He clearly distinguished cases of hemiplegia cerebralis spastica and paraplegia cerebralis spastica, using these expressive names which have since been employed with minor modifications by Benedickt, Bernhardt and others. At page 163 of his monograph is also to be found, perhaps the first, certainly a most accurate, account of post-hemiplegic movements.

Little, the well-known London orthopœdic surgeon, has contributed more than any one to the subject, and to him we owe, in great part, the accurate knowledge of the relation of the cases to abnormal parturition. His paper in vol. iii. of the London Obstetrical Society's *Transactions*, 1862, contains an immense amount of material. The clinical description which he gives at pages 301–303 has not been excelled. In France the cases of spastic rigidity are sometimes called Little's disease (maladie de Little). The writings of Delpech,[1] Stromeyer[2] and Adams,[3] particularly of the latter, to whom we owe the name spastic paralyses of children, contain careful descriptions; and more recently Rupprecht[4] has considered the subject from a surgical standpoint.

Bilateral hemiplegia is characterized by a spastic condition of the extremities, dating from or shortly succeeding birth; occasionally following the specific fevers or an attack of convulsions. The legs are more involved than the arms; there is no wasting; no disturbance of sensation; the reflexes are increased. The mental condition is profoundly disturbed; the patients are usually imbeciles or idiots, helpless in mind and body. Ataxic and athetoid movements of the most exaggerated kind may occur.

Anatomically there is bilateral sclerosis or porencephalous defect of motor areas of the cortex cerebri.

Case I.—Anna S., æt. three and a half years. First child; no instruments used in labor; full term. An "inward convulsion" on tenth day; lay for three days apparently dead. First teeth came at sixth month. Child has not progressed well. Head seventeen and a half inches in circumference.

February 29, 1888. Aged now six years; says only "mamma," "papa" and "no." Strabismus, no nystagmus. Has thriven and grown, understands everything. Head long and narrow; biparietal diameter five inches; occipito-frontal six and a quarter inches; circumference eighteen and a half inches. Face blank, but laughs. Conjunctivitis; teeth bad. Uses hands to eat; arms stiff at elbows. Legs stiff in extension. Well nourished. When cries gets very rigid. Pes equino-varus. Feet cross when attempts to stand; cannot walk; knee-jerk +, no clonus.

Case II.—Amelia P., æt. fourteen months. M. 5, 423. Born at seven months; no instruments; reason assigned for miscarriage carrying a heavy weight. First child. Great weakness noticed at birth, but nothing else; child very small; no spasms; has never had any serious illness; has never cut any teeth; never walked; never talked, except for the last two months to say "papa" and "mamma." Convergent strabismus. Never has had any skin eruption. Keeps the legs crossed. Recognizes the parents; does not fix attention; does not sit up well; wabbles the head about. Knee-jerk ++. Plantar reflex

[4] Rupprecht: Ueber angeborne spastische Gliederstarre und spastische Contracturen, Volkmann's klin. Vorträge, No. 198.

+. Head microcephalic, symmetrical; fontanelles closed; circumference of head seventeen and a half inches; occipito-frontal diameter six inches; biparietal diameter five and a half inches; bridge of nose sunken. Arms and legs stiff, moves them with freedom; takes things with the left hand, does not grasp well; right arm especially stiff at shoulder and elbow; while under observation legs stiffened in extension; in the interval the legs can be extended and flexed easily; stands fairly well when supported.

Case III.—Everett A. P., æt. five years. Parents alive and healthy; no nervous diseases in family. This child is the oldest of three. Born at seven months; no instruments; small, very weak, jaundiced. Noticed stiffness when only a week or two old, in legs and arms; has never walked. Does not know his letters. Never had a spasm; had scarlet fever. Hands have always been free from spasm; elbows stiffer sometimes than at others. Temper not very good. *Status præsens:* Legs; color, temperature, nutrition good. Knees, ankles and hips stiff; cannot walk, when supported stands on toes with legs crossed. Spasm in facial muscles at times. Knee-jerk +. Can use hands well; elbows stiff. Cremasteric and abdominal reflexes present. Spine straight. Phimosis; teeth fair. No nystagmus. Bright, talks well. Head—biparietal diameter five and a half inches; occipito-frontal seven inches; circumference nineteen and three-quarters inches. In bed sits with spine doubled, cannot sit up straight.

Case IV.—Florence S., æt. four years. M. 5, 137. No forceps used. No trouble during pregnancy. Five older children. Father and mother healthy. Nothing special about child at birth; nursed well. Spasms on the second day. Has not walked or crept. Does not talk; understands what is said. Is well nourished; fairly well grown child; looks bright, and is fairly intelligent, though expression is spoilt by the constant dribbling from the open mouth. Head wabbles from side to side. Head measures nineteen and a half inches in circumference, and is symmetrical. Sutures closed, and a little ridged in their course. Arms not well developed, and are stiff, but can be readily flexed at elbows, wrists and fingers. Gets so stiff at times that she can be lifted without bending. Arms stiffen in extension. Moderate grasping power. Knees and thighs can be flexed, abducted and adducted. Like arms, they stiffen and get hard. Cannot walk. Plantar reflexes not marked. No ankle clonus. Knee-jerk +. Teeth much decayed. No convulsions now. Sleeps well, but will not sleep in the dark, and awakens at once if light is removed.

February 4, 1888. Will be six years old in August. Is small for her age. Does not get so stiff now, only once or twice a day, not, as before, a dozen times. Very characteristic posture of legs—feet extended and legs crossed. Stands on toes, generally on right foot, with the left leg diagonally across the right. Holds her head better; is not so cross. Hands get stiff, and fingers separate and extend when she attempts to take anything.

Case V.—Jennie S., æt. ten years. M. 7, 177. Labor difficult. Head much flattened in birth, and child was unconscious for half an hour. First child. Second died at four years from accident. Mother thinks child always used arms and legs with difficulty. Never learned to walk or use the hands. Dentition natural. Intellect deficient, yet understands ordinary conversation. Has not learned anything. Knee-jerk ++; muscles rigid; arms and legs almost contractured. Color pale, appetite good, sleeps well. Bowels regular. Heart normal. Lower jaw retreats: Occipito-frontal diameter, six and a half inches; occipito-mental diameter, eight and a quarter inches; biparietal diameter, five inches.

Case VI.—Lydia B., æt. two years and three months. M., 158. Elder of two children, other healthy. Born without instruments. Head slightly microcephalic. Biparietal diameter, four and three-quarters inches; occipito-frontal, five and a half inches. Fontanelles closed. Forehead prominent in central portion. Internal strabismus. Mouth open, no dribbling. Intelligence poor, speaks little, smiles and looks intelligent. Dentition began at six months, last tooth is being cut now. Arms stiff, especially left. For a time kept left hand closed. Legs stiff, slight extension of feet. Tendency to talipes equinus, legs flexed with difficulty, sits with legs crossed. Never has used legs properly; they are thin and cold. *Electrical examination:* Quantitative change, but no reaction of degeneration; had a spasm soon after first visit; tendon reflexes increased.

Case VII.—Nellie M., æt. six years. M. 5, 291. Mother died of phthisis; one child died at eleven months, of convulsions, while teething. This child is one of twins, the other born dead. Some defect noticed at birth; teething natural. Never had convulsions. Never has been able to sit up or walk; has to be fed. Right hand weak and small, can take some things in it. Both shoulders stiff, a little pressure relaxes them. Thighs are crossed. Legs have clasp-knife rigidity; left leg crosses right; this position is nearly constant. Legs can, however, be placed side by side; right leg decidedly larger than left. Foot strongly extended on leg; ankle-joint cannot be flexed. Knee-jerk ++; no ankle clonus. Expression idiotic; speaks no word; temper bad; mouth open; constant dribbling; does not cry much. Head microcephalic, supro-orbital arches marked. Face prognathous. Forehead low, narrow; does not support head, but it wabbles from side to side. Circumference of head, seventeen and a half inches. Chest rickety, costal margins everted; sternum depressed; antero-posterior and lateral spinal curvature. Convergent strabismus, nystagmus.

Case VIII.—Harry B., æt. one year. M. 5, 168. One brother said to have some brain trouble, one died in a convulsion at the age of three years, one died of congestion of brain. Two other healthy children. Fourth child; labor natural. Was backward about walking. Since summer of 1885 has twitched hands and feet. Head symmetrical, measures nineteen inches; expression bright and intelligent. Temper good. Makes no sounds, seldom cries. Uses his hands well; at times clinches hands and folds them over heart, and they get stiff. Eyes turned a little. Moves feet with a slight spasmodic movement. Legs cross when at rest, when he is lifted they get stiff.

Case IX.—Wm. R., æt. two years. M. 4, 33. Family history good. Mother had a severe fall five months before child was born. Never has had any children's diseases. Is moderately well nourished. Special senses perfect; dull, stupid, never says anything except "mamma." During last year has had frequent attacks, in which face grows at first scarlet, then purple, and finally white. Attacks last from two to three minutes, during which he works mouth and twists lips. There is entire loss of consciousness. Does not bite tongue or froth at mouth;

attacks occur in daytime; sleeps after them. Independently of these attacks during the day he has repeated spasms of the muscles at the back of the neck, and the head is drawn into complete extension. There is a constant spasm of the left thumb, which is drawn across the palm of the hand. Arms stiff. Legs tend to cross when he is held erect, but can be spread apart by force; great difficulty in flexing the legs when they are in spasm. Cannot stand alone, and has never walked more than two or three steps. Uses hands but little, holds objects in an awkward manner, and cannot feed himself. Still nurses, but takes other food. Slight nystagmus. Dribbles constantly. Sleeps well, but starts at sounds; is constipated.

Case X.—Morris C., æt. three years. M. 4, 122. First child; labor lasted eleven hours; instrumental. Father thinks mother was frightened when half way through pregnancy. Child's body was black when born. He cried continuously for one week after birth. When he began to move, parents noticed his movements were awkward. Cannot sit up. Has no fits now; is said to have had them last fall. Appetite and sleep good; shows signs of intelligence. Eyes squint internally. February 15, 1888: Returns to-day. Is now eight years old. General health has been good; no convulsions; has not been able to sit up, nor walk; lays on stomach in cot-bed most of the time; cries very little, temper good; can scarcely talk, says a few words—*e.g.*, "home," "all right," "hello." Looks fairly bright and intelligent, understands what is said. Head not quite symmetrical; left parietal and left frontal eminences most marked. Biparietal diameter, five inches; occipito-frontal diameter, seven and one-quarter inches; circumference of head, nineteen and a half inches. Eyes bright, clear, slight convergent strabismus; pupils medium size, react to light, vision seems good. Makes irregular movements of lower muscles of face; opens mouth, and utters unintelligible sounds. Has difficulty in supporting head, which wabbles from side to side. Does not appear to be distinct spasm of these muscles. Back much turned to right. No wasting; body is thin. Hands are held closed, opens them sometimes; thumb inverted, and fingers usually closed over it; is unable to grasp anything. There are constant, large, irregular movements of arms; distinct spasm in arm; very difficult to extend forearm. Right thigh constantly drawn up in semiflexed position; leg flexed on thigh; left leg extended, foot inverted, great stiffness; muscles of legs fully developed, but firm. Knee-jerk +; no ankle clonus. Teeth good, getting second set.

Case XI.—Thos. McG., æt. four years. M. 5, 195. One of three children. No phthisis in family. Born naturally, and seemed healthy. Measles at three months, followed by hydrocephalus; head continued to increase in size till one year old; circumference twenty-three and a half inches. Dentition normal. Talked at an early age and seemed quite bright. Never walked, but can kick legs; legs spastic on standing, toes extended, muscles tight, feet crossed, legs relaxed when at rest. Knee-jerk + +. Hands shake and arms are stiff.

Case XII.—Elsie J., æt. one and a third years. M. 5, 216, Roxborough. Youngest of two children, the others perfectly well. Labor natural and not difficult. Never had convulsions; no definite onset. Head microcephalic, measures seventeen and a quarter inches in circumference; furrow in temporal region; sutures closed for some time; transverse diameter above ears four and a half inches; occipito-frontal, six inches. Dentition retarded. Has upper incisors and lower central. Seems bright and notices objects. No nystagmus. Fairly well nourished. Arms stiff at elbows and shoulders; knee-jerk +. Legs were noticed to be stiff soon after birth; not well developed; never walked; on standing rests on toes (Fig. 1);

FIG. 1.

Position of child when supported.

knife-clasp rigidity; strong adduction; sometimes crosses legs; some eversion of feet; attempts to walk; seems to have more power on left side. January 31, 1887: Supposed to have had spasms about a year ago; was three years old last December. Arms and legs remain stiff. Child has not developed mentally.

Case XIII.—Willie L., æt. six years. One child stillborn; one, aged two weeks, died of marasmus. Born with instruments; had fits as soon as born, lasting for three days; moved arms and legs, but not so well as other children; never able to sit up till one year old; began to talk at two years; sat up and held up head at eighteen months; right hand contracted till second year; dragged the right hand in creeping; stood at three and a half years; cannot stand now without support. Intellect bright; speech affected, has difficulty in pronouncing words. Fits again two years ago, after improper food. Healthy but small. Back straight; walks on toes; legs small below knees; skin and tissues adherent; contraction of tendo Achillis, which can easily be overcome. Legs cold; in walking toes of left foot turn in; left hand rather the larger; both arms stiff.

Case XIV.—Fred. H., æt. three years. M. 7, 58. Parents healthy, five other children, all well. Looks bright; understands everything. Born at seven months; no instruments; nursed by mother. Has never sat up, crawled or walked; is now just beginning to say a few words. Restless and irritable; constantly throws himself backward. Hands and arms contracted and stiff, and in

constant motion; makes an offer to take things, but can scarcely take anything to his mouth as the arms are so stiff, left more than right; feet are at times everted (*i. e.*, valgus), then the toes are flexed and extended. Knee-jerk difficult to obtain; no ankle clonus; spasm gets less when once overcome by motion; teeth good; no nystagmus. Biparietal, four and three-quarters inches; occipito-frontal, seven inches; occipital region very prominent; circumference nineteen and a quarter inches. He has been sick lately with fever; is now very pale; at times gets very stiff arms and legs; hands and fingers extend and get rigid; uses left hand most; can scarcely grasp an object. Has had two slight convulsions, limited almost entirely to face and mouth, first last fall (1886), second in March, 1887.

Case XV.—Ralph W., æt. three years and six months. In Pennsylvania Institute for Feeble-minded Children. Idiot; no history; unable to walk or talk. Head microcephalic, circumference sixteen and a half inches, with the hair; no nystagmus; does not dribble; teeth good; arms rigid, and become more so on the slightest touch; irregular movements in fingers, but how much voluntary and how much involuntary, it is difficult to say; legs in extreme spasm, slight equino-varus position; the feet can scarcely be moved, so firm is the extensor spasm; the whole pelvis moves on attempting to flex the thighs.

A class of cases belonging to this division of bilateral hemiplegia is characterized by *spasm and disordered movement*. They are described in literature as *chorea spastica and double athetosis*. The cases I refer to are simply spastic diplegias, plus post-hemiplegic disorders of movement. The history is the same as in ordinary cases; the trouble has persisted from birth or shortly after, and there is a condition of feeble-mindedness or idiocy, though in some instances the intelligence is fair. Very often, too, there has been a difficult labor.

Of the chorea spastica, the following are probably illustrations:

Case XVI.—Mary M., æt. four years. M. 4,429. Breech presentation, delay at the head, was six hours before she was resuscitated. Began to talk at two years; never walked; almost from birth she has had peculiar movements of hands and arms; the thumbs are turned in and there is constant irregular motion of the arms and hands, with stiffness, which is made worse when she attempts to control it; it is like a chorea. There is also some incoördination of the head. She is well nourished; no wasting. Coördination of legs good; but she does not walk.

Case XVII.—Nellie P., æt. nine years. I. P. b., 55. Parents healthy, five children dead, of seven. Seven years ago had fits while teething, had fits constantly for twenty-one days; for nine months had seven to nine per diem; in very weak health when fits ceased. *Present state:* Speech hesitating; memory not affected; unable to stand, sit, feed herself or assist herself in any way; can move every muscle in the body, but with an irregular movement which prevents her using any group of muscles; the movement is choreoid; in attempting to grasp an object the fingers are thrown out in a stiff, spasmodic and irregular manner, and she is unable to close them over the object.

I do not mean to infer that all cases of so-called congenital chorea come under this designation; there are instances without spastic rigidity, as the case reported by Dr. Sinkler from this hospital.[1] Certain of these cases of congenital chorea have also had definite athetoid movements.[2]

There are several reports of children in the Infirmary records with the diagnosis of multiple seclerosis, which in many respects resemble these cases, and it would doubtless often be difficult to make a differential diagnosis.

Bilateral athetosis is not very uncommon; an illustration may be found in almost every almshouse or home for incurables. It is one of the most distressing of all maladies to witness, and is usually associated with imbecility.

The following cases illustrate the combination of spasm with disordered movement characteristic of this condition.

Case XVIII.—William B., æt. thirty. In the Elwyn Institution for eight and a half years. History: Had jaundice when eleven days old, after which the paralysis occurred. *Status præsens:* Intelligent looking; head well formed. Does not speak, but utters a loud, deep-toned sound when he is pleased. Sits up, but in a sloping position. Cannot stand. Continual grimaces, caused by irregular movements of the lower face muscles. Head is turned forcibly from side to side and the mouth drawn and hideously distorted. Arms very stiff, not wasted; are quiet at times, but every few minutes the most irregular movements; the arms and forearms stiffen in extension, the hand flexed, and the fingers in rapid, continuous spasm. At times is quite quiet and can even feed himself. Sits usually with his wrists strongly flexed on the bench, as if helping to support himself. The motions of the fingers are typically athetoid; those of one hand will be flexed on the palm while the others are in active extension. As he feeds himself the spasm is very great, and it is with much effort that the mouth and hand can be made to meet. The index finger may be strongly flexed while the middle is in extreme extension. The legs are stiff, strongly adducted. The feet are in extension in equino-varus position. The knee-jerk is obtained with difficulty. He is good-tempered and smiles; knows the attendants and makes signs as to his wants.

Case XIX.—Laura C., æt. twenty-one. The fifth child. A hard labor, but no instruments used. When born there was "no sign of life in her," and for an hour she was blue. The mother is a large, well-built woman; the family history is excellent. At six months the child had whooping-cough; seemed weak before this, but after the attack grew much worse; could not sit up and could not help herself like other children. From infancy she has had irregular movements of the arms and legs, with stiffness. Learned to talk late; is intelligent and good-tempered. She was brought to the infirmary when eleven years old. When seen recently at home she presented the following condition: a medium-sized girl, pale, but with an intelligent face. Sits in a chair supported by cushions. She answers questions in an interrupted, somewhat high-pitched voice, a little difficult to understand at first. Mentally is quite bright; appreciates her condition, and said she was a "little Job." Likes to be read to and to play with the children. She has never walked, and is quite helpless on account

[1] System of Medicine; edited by Pepper. Vol. v., Phila., 1886.
[2] Rau: Neurologisches Centralblatt, 1887.

of the extraordinary rigidity and irregular movements of the extremities, which are excited by emotion or by any attempts at voluntary efforts. The facial muscles move spasmodically as she speaks. When pleased she laughs in a loud, rough manner, with the mouth widely opened, the jaw strongly depressed, so that the uvula and palate are freely exposed. The arms are well nourished and are held in strong extensor spasm; the left is rotated inward and rigid; the forearm is so strongly extended that there is almost an anterior dislocation of the elbow-joint. At the same time there is extreme rotation of the radius and the hand, the fingers of which are clinched so tightly that it is impossible to separate them. The right arm is less strongly contracted, and with it she can make attempts to grasp objects. The spasm relaxes every few moments and the limbs assume new attitudes. The fingers relax and close, but without that continuous, orderly spasm seen in typical athetosis. The shoulder and trunk muscles are also affected, and their irregular contraction moves the trunk about from side to side. The legs are strongly extended, the feet in the equino-varus position. There is not much movement, but on testing the reflexes there were sudden spasmodic jerkings, and at times the knees are drawn up. The muscles in spasm have an iron-like rigidity, and it is almost impossible to bend the limbs. When not excited she is much quieter and the muscles relax; but the slightest exertion brings on the spasms. She can sometimes, with the left hand, pick up objects and even carry a biscuit to her mouth, but she is quite unable to feed or help herself. The arm and leg reflexes are increased; the ankle clonus is readily obtained. Sensation perfect; the most extreme spasm gives no pain. There are no trophic changes. Her appetite is good and she sleeps well, the contractions disappearing completely. The bodily functions are well performed.

Some of these cases were able to walk, and in all the hands were used awkwardly, or not at all. The legs are most affected, usually extended, the feet crossed and in the pes equinus or equino-varus position. The thighs are often strongly adducted—the so-called clasp-knife rigidity. When the child sits the legs cross, and, if supported, there is the characteristic attitude of infantile spastic paraplegia, the feet crossed and the body supported on the toes. In Case X. the right thigh was drawn up; sometimes the legs are partially flexed, but, as a rule, the extension position is maintained. The stiffness is in some cases constant, while in others it varies greatly and is increased when the child cries, or in attempts to move. It may be more marked on one side than on the other. The whole body may at times become rigid, and, as Little remarks, is turned "all of a piece" on the lap. The arms are usually flexed, and the stiffness is at once apparent on attempting to extend them. It may be difficult or impossible to raise the arms or to abduct them. The hands may be clenched and the fingers strongly flexed, but it is rare to see the extreme spasm which is so common in hemiplegia; and, as the reports indicate, a majority of the children could use the hands, though awkwardly; while in Case III. the movements were almost natural. There may be, as in Case X., large, irregular movements of the hands.

Spasm of the muscles of the face or tongue was rarely noted. In Case X. there were irregular movements of the facial muscles; and a condition of rigidity was at times present in the facial muscles. The spasm is not always fully relaxed during sleep, but disappears when the patient is fully etherized. The back and neck muscles are weak, and the child is rarely able to sit up alone. The spine in some cases seems to have remarkable flexibility, and mothers have used more than once the expression that the child was as "limp as a rag." So helpless, indeed, is the condition of many cases that unless in bed they must be in the lap. The feeble neck muscles are unable to support the head, which rolls from side to side or sinks on to the chest. The muscles were firm and hard, not often marked wasting.

In no case was sensation impaired.

The reflexes were increased in all these cases, particularly the knee-jerk. The ankle clonus cannot, as a rule, be obtained.

The electrical conditions in the cases tested were unchanged.

With the exception of Case III., the children were either idiots, without a glimmer of intelligence, or imbeciles. The facial expression usually indicated the mental deficiency. The open mouth, constantly dribbling saliva and lolling tongue were present in the majority of the cases. Only two of the children could speak plainly, thirteen could not talk at all and four could say only a few simple words. With the exception of two or three cases, they all seemed to be able to understand, more or less, when spoken to by their mothers. Irritability of temper was complained of very much.

Microcephalus is a very common condition with asymmetry, and in several of the cases the head was very broad above and behind the ears.

In two cases nystagmus existed, and in three strabismus.

As is so common in imbecile children, the teeth were defective, a condition to which Dr. Alice Sollier has recently devoted a special monograph.[1]

Only two children had epilepsy, Case IX., subject to attacks of *petit mal*, and Case XIII., which had two spasms in which the face twitched, and the child seemed to lose consciousness. Cases I. and IV. had had convulsions after birth, and Case X. had fits at two years of age.

Of these nineteen cases the youngest at the time of application was one year and the oldest ten. Six were first children; three were born at seven months; in three cases the labor was prolonged, in two of which forceps were applied; one was a breech case. In eight cases the labor is stated to have been natural.

In ten of the cases the condition was probably congenital, as there was no definite onset, and the stiffness was noted early. In Case I. there were convulsions on the tenth day, and the child was unconscious for three days. In Case VI. the head was much flattened by the forceps, and the child could not be roused for half an hour. In Case X., also, the child was delivered with forceps, was asphyxiated when born, and cried for a week. In Case XI. the child had measles at three months, which was followed by hydrocephalus and the gradual development of a spastic condition.

I have been able to collect the reports of sixteen autopsies in cases of bilateral spastic hemiplegia in children;

1 De l'état de la Dentition chez les Enfants Idiots et Arriérés. Paris, 1887.

the youngest was two years old, the oldest thirty. The anatomical condition in these cases was as follows: Case I. F., æt. five years (Kundrat[1]). Bilateral porencephalus, motor regions. Case II. (Henoch[2]) M., æt. six. Atrophy, frontal convolutions. Case III. (Heubner[3]) æt. two and one-half. Atrophy of left central and right parietal convolutions. Case IV. (Ross[4]) F., æt. two and one-half. Bilateral porencephalus. Case V. (McNutt[5]), F., æt. two and one-half. Bilateral atrophy, central convolutions. Case VI. (Richardiere[6]) F., æt. two and one-half. Sclerosis of temporo-occipital and parietal gyri on both sides. Case VII. (Isambert and Robin[7]), æt. two. General cortical sclerosis of both hemispheres. Case VIII. (Bourneville[8]), æt. ten. Extreme sclerotic atrophy in both hemispheres. Case IX. (Bourneville[8]), æt. nine. Bilateral atrophy of convolutions, particularly the central gyri. Case X. (Blanchez[9]) F., æt. five. Atrophy of posterior lobes of both hemispheres. Case XI. (Simon[10]), æt. two and one-half. Sclerosis of central convolutions. Case XII. (Bourneville[8]), æt. five and one-half. Foci of sclerosis in frontal and temporal lobes. Case XIII. (Ashby[11]), æt. twenty-two months. General atrophy; surface of hemispheres smooth. Case XIV. (Moore[12]), æt. five. General cortical sclerosis. Case XV. (Gee[13]) F., æt. eleven. General cortical sclerosis. Case XVI. (Mierzejewsky[14]), æt. thirty. Double porencephalus.

A more detailed account of Dr. Sarah J. McNutt's case will illustrate the condition which exists in the majority of these patients. The child, two and one-half years old, had been delivered with instruments and had convulsions during the first nine days of its life, and for a long time did not seem to have any muscular power. When first observed there was paresis with rigidity of all the extremities, and the child was defective mentally. Death occurred from gastro-intestinal catarrh. The brain was studied by Dr. William H. Welch, who has given a very full description of the coarse and microscopic appearances. There was atrophy in each hemisphere of the paracentral lobule, of the central convolutions and of the roots of the three frontal convolutions. Microscopically the cortex of the affected convolutions was replaced by a finely fibrillated tissue, rich in nuclei and without ganglion cells and nerve fibres. There was typical bilateral secondary degeneration of the pyramidal tracts in the pons and medulla and cord. In the pons most of the bundles of the longitudinal fibres were degenerated, in the medulla the sclerosis was confined to the anterior pyramids, and in the cord the degeneration involved the direct and pyramidal fasciculi on both sides. The ganglion cells of the anterior horns were normal in number, size and general appearance.

Destruction of the motor centres of the cortex is, then, the essential lesion in bilateral spastic hemiplegia. Diffuse atrophic sclerosis is the most common condition; a patchy sclerosis has been found in some cases; porencephalia in others, while in Ashby's case there appears to have been arrest of development, as the surface of the hemispheres was smooth and sclerotic. Descending degeneration has been found in the pyramidal tracts in the cases of McNutt, Jules Simon and Ashby. In the majority of the cases there was no report as to the condition of the cord. In Ross's case the cord did not show any changes.

Voisin[1], in 1884, communicated to the Paris Academy of Medicine a note on the morbid anatomy of five cases of this kind. No details were given, merely the statement that the condition was caused by arrest of development and atrophy of the central gyri. I have not been able to find a full report of his paper.

ORIGINAL ARTICLES.

A CASE OF POTT'S DISEASE, PRESENTING IN THE ARMS SYMPTOMS RESEMBLING THOSE OF LOCOMOTOR ATAXIA, AND IN THE LEGS THOSE OF SPINAL SPASMODIC PARALYSIS.

BY HENRY HUN, M.D.,
PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM AND OF PSYCHOLOGICAL MEDICINE IN THE ALBANY MEDICAL COLLEGE.

IN THE MEDICAL NEWS of April 21, 1888, Dr. S. Weir Mitchell published a very interesting account of a case of "locomotor ataxia confined to the arms." The following case bears some resemblance to that of Dr. Mitchell's, but in many respects it differs from it and from any case which I have been able to find reported.

P. Z., aged thirty-four, single, a cooper by trade, entered St. Peter's Hospital, December 9, 1887. He had always enjoyed good health till twelve years ago, when he had a fever, from which he made a good recovery, and continued well till two years ago, when he was obliged to give up work on account of a severe pain in his back between the shoulders. During the past two years he has gradually grown weaker, but was able to walk without assistance till two months ago, since which time he has felt as though there was a tight band about the abdomen, and has been unable to walk without the aid of a chair. He has been much troubled by pains in his arms, he sometimes sees double, and when he walks he is dizzy. He is constipated, and micturition is a little sluggish at times. No venereal history.

Patient is a well-nourished man. He sits with his head bent forward, and raises it with difficulty. Pupils are dilated and equal. No paralysis or abnormality in the domain of any cranial nerve. There is a fair amount of strength, moderate anæsthesia

[1] Bulletin de l'Academie de Médecine, 1884.

and analgesia, and very decided ataxia and loss of muscular sense of arms and hands. No anæsthesia of legs and feet. Muscles of legs weak. He cannot walk without assistance. Very slight, if any, ataxia of legs. Knee-jerk and ankle-clonus greatly exaggerated; so that a slight tap on the ball of one foot causes both legs to tremble and shake violently for a long time, presenting a beautiful example of the so-called "spinal epilepsy." Plantar and cremasteric reflexes increased, umbilical reflexes faint. No atrophy of the muscles of either arms or legs. The spinous processes of the second, third and fourth dorsal vertebræ are decidedly prominent, and that of the fourth is tender. Dr. S. R. Morrow, the attending surgeon of the hospital, having examined the spinal deformity, pronounced it an undoubted case of Pott's disease.

Jan. 19. Patient is rather worse. The cranial nerves continue to be unaffected. There is a fair amount of strength, complete anæsthesia and almost complete analgesia and a great degree of ataxia of arms and hands. When the patient is asked to touch his nose while his eyes are shut, he is quite as likely to touch his ear or his shoulder. Absolute loss of muscular sense; so that when his eyes are shut, the patient is in complete ignorance of what position his arms are in. Slight anæsthesia of upper half of thorax. A patch of indolent congested and excoriated tissue, resembling a bedsore, is on the top of the right shoulder. Movements of the legs are weak and very slightly ataxic. A slight degree of anæsthesia of legs. There is no decided loss of muscular sense, inasmuch as the patient can always tell the position of his legs when his eyes are shut; but he cannot tell when his toes are moved passively. Knee-jerk and ankle-clonus are greatly exaggerated. Umbilical reflex faint, cremasteric reflex normal, and plantar reflex absent. No muscular atrophy in arms or legs.

Feb. 29. The condition of the patient has not materially changed during the past month, except that the tendon reflexes in the legs are not as exaggerated as they were, and he no longer presents the beautiful example of "spinal epilepsy" that he did. The spinal curvature has continued unchanged. In regard to treatment the patient has been kept on his back in bed. During the first month, he took nitrate of silver grs. ij, t. i. d., and during the second month, iodide of potassium grs. xv, t. i. d. Dry cups and hot water were applied to the back, and the galvanic current to the arms and legs. He has had several slight hæmoptyses, and, on examination, the left clavicle is found to be prominent, and there are dulness and broncho-vesicular respiratory murmur with an occasional moist râle after cough at the left apex. He became dissatisfied and left the hospital to-day, and soon afterward went to Cleveland, Ohio.

Early in May, Dr. Henry S. Upson, of Cleveland, Ohio, sent me the results of an examination which he very kindly made of this patient at my request. He found in both legs muscular weakness without atrophy, normal cutaneous reflexes, greatly exaggerated tendon reflexes, and preservation of tactile, painful and muscular sensibility; in both arms ataxia, anæsthesia, analgesia, loss of muscular sensibility, slight atrophy of the dorsal interossei, supra-spinatus and trapezius muscles on the right side, fibrillary contraction of the left supra-spinatus muscle and of the muscles in both arms; the muscles of the forearm responded to mechanical excitation, and there were exaggerated tendon reflexes at both elbows and wrists. All the muscles responded to both the faradic and galvanic current, except some of the deep muscles on the right side of the neck, which did not respond to either kind of current. Pupils reacted both to light and to accommodation, and an ophthalmoscopic examination revealed nothing abnormal.

When this patient entered the hospital, he presented the very remarkable clinical picture of locomotor ataxia in the arms, and of spinal spasmodic paralysis in the legs. The angular curvature of the spine, the hæmoptyses and the physical signs of pulmonary tuberculosis, taken in connection with the paraplegia, gave pretty conclusive evidence that a tubercular disease of the vertebræ was present, the products of which had given rise to a compression of the spinal cord (or to a compression myelitis) in the upper dorsal region. It is evident that the symptoms in the legs were all easily explicable by the compression. As is common in such cases, there was little or no disturbance of sensibility; the compression affecting more especially the anterior part of the cord and not involving the sensory fibres of the legs in the columns of Goll. It is possible that a descending degeneration of the crossed pyramidal tract (which at the autopsy of such cases of compression of the spinal cord is usually found running throughout the whole length of the cord below the compressed portion and even for a short distance above it) may have helped to cause not only the muscular weakness but especially the greatly exaggerated tendon reflexes. Later in the course of the disease, and while the patient was under observation in the hospital, the columns of Goll became slightly involved, giving rise to the symptoms of impaired sensibility in the legs, which, although slight, were quite evident on January 19th.

The compression was evidently situated at the spinal deformity, which was just below the cervical enlargement, but the symptoms in the arms could scarcely be due to a simple direct extension of the softening or the inflammation upward, for in that case the anterior parts of the cord would have been affected as much as, or even more than the posterior (since they were more involved at the point of compression), and would have produced muscular paralysis and atrophy of the muscles of the arms. A possible explanation of the fact that the posterior rather than the anterior horns were involved may be that the fibres of those sensory nerve roots in the posterior horns and in the columns of Burdach,

which were involved in the compression, had degenerated above this point, and that this ascending degeneration (which is usually found at the autopsy of cases of compression of the spinal cord) and consequent sclerosis had extended by contiguity to neighboring fibres and had caused a sclerosis of the posterior horns and columns of Burdach in the cervical enlargement, which gave rise to the symptoms resembling those of locomotor ataxia in the arms. It seems in this case as if the posterior horns were much more involved by the disease than the columns of Burdach, for the anæsthesia and analgesia were more complete and widespread than is usually the case in locomotor ataxia, and Dr. Upson found when the patient was in Cleveland that the tendon reflexes were not only not absent, but were exaggerated.

In regard to the knee-jerk, Westphal[1] has shown that in cases of locomotor ataxia its absence depends upon a lesion of the lateral portion of the columns of Burdach, which he calls the "zone where the roots enter" (Wurzeleintrittszone), at the junction of the dorsal and lumbar regions of the cord. He gives figures of the lesions in five cases of locomotor ataxia, in which the knee-jerk was preserved either throughout the disease or until very late in its course, and in which this zone was either entirely free from disease or had only just commenced to be involved by it. Probably the tendon reflexes in the arms depend on the integrity of a similar zone in the columns of Burdach in the cervical region of the cord, and the existence of these reflexes in this case proves that this zone is not diseased.

When Dr. Upson saw the case, the symptoms in the arms and neck indicated that the anterior horns were also being slowly encroached upon by the disease, but the signs of disease of the anterior horns, even at that late date, were very slight in comparison to those of the posterior horns; and it seems as if the extension upward of the inflammation in the posterior rather than in the anterior part of the cord might have been determined or brought about by the ascending degeneration which usually occurs in cases of compression of the spinal cord. It is not probable that this sclerosis would extend by contiguity for any great distance in the posterior horns and in the columns of Burdach, so that a compression of the spinal cord must be seated immediately below the cervical enlargement to produce the symptoms which it apparently produced in this case. It is certainly a case in which the diagnosis needs to be confirmed by an autopsy, but inasmuch as I shall, in all probability, never see the autopsy, even if one should be held, I publish the clinical history of this, to me at least, very uncommon case.

TWO CASES OF THE RADICAL CURE OF HERNIA.[1]

BY J. WILLIAM WHITE, M.D.,
SURGEON TO THE PHILADELPHIA AND GERMAN HOSPITALS; ASSISTANT SURGEON TO THE UNIVERSITY HOSPITAL.

G. B., male, farmer, aged forty-one, was admitted to the wards of the German Hospital on the evening of March 27, 1888, with the following history: For ten or fifteen years he had had a large swelling occupying the right half of the scrotum and extending upward to the neighborhood of the internal abdominal ring. During all this time this swelling had never entirely disappeared, although it varied in size and consistency. He had suffered no great inconvenience from it, except that due to its bulk, until about thirty-six hours previous to his admission, at which time it had suddenly become painful, much increased in tension, and a groove or furrow had developed midway between the base of the swelling and its origin above Poupart's ligament. The whole scrotal tumor was very tense, and nothing beneath the skin could be distinctly felt on palpation, though the lower portion gave the impression of containing fluid. There was a certain amount of resonance on percussion from the middle to the upper part of the swelling, the lower third being dull. In addition to the local symptoms, the man at the time of his admission into the hospital had persistent retching and vomiting, which had then lasted for twenty-four hours; the matters ejected were fluid, sour, offensive, but not distinctly feculent. A diagnosis of complete oblique inguinal hernia, strangulated in the sac, was made, and herniotomy was proceeded with.

A long incision was made beginning an inch above the situation of the internal ring and extending obliquely to the base of the tumor. The usual layers of tissue were divided until the sac was reached and opened. A constriction was found, as had been expected, at the point where the transverse groove was situated, which was due to bands of infiltrated lymph binding the inner surface of the sac to the closely adherent intestine. It was with great difficulty that the extreme tip of the finger-nail could be inserted at this point to serve as a guide for the probe-pointed bistoury, which was made to follow the finger and finally to divide a portion of these bands. Finding the constriction remaining, it became necessary to dissect down carefully from the outside, with light touches of the bistoury, until the lymph bands were completely divided; after this the separation of the bowel from the interior of the sac became comparatively easy, and was accomplished by the fingers without the aid of other instruments. At the level of both rings the intestine was found entirely free. As soon as the knuckle of gut below the constriction was drawn into view it was followed by an extensive gush of fluid, slightly blood-stained, and resembling that seen in hydrocele. The finger, following the sac to its base, easily recognized a rounded glandular mass about the size of a walnut, which was at first thought to be an atrophied testicle, this view being apparently supported by the existence of a fleshy cord in the sac extending its full

[1] Read before the Pennsylvania State Medical Society, June 6, 1888.

length, emerging from the upper ring and running to the gland mentioned, and containing a hard wire-like body which was then thought to be the vas deferens, and certainly was absolutely indistinguishable from that duct by the sense of touch.

At this juncture it was very natural to suppose that the hernia was of the congenital variety, the sac of the hernia and the tunica vaginalis being continuous. The existence of the supposed cord and the large quantity of fluid, together with the history of the case, all favored this view. A little later, however, all tension being then removed and the scrotal tissues easily subjected to palpation, both testicles were found to be *in situ*, the one on the affected side being below and behind the region exposed by the operation. Closer inspection then revealed the fact that the supposed testicle was an enlarged, indurated mesenteric gland communicating with a lymphatic vessel, also greatly enlarged and indurated by long-continued inflammation, giving it its wire-like feel; the fleshy tissue, thought to be the cord, proved to be a mass of omentum, which during its many years of irreducibility had become rounded and agglutinated so that it had lost all its special characteristics. This was ligated high up and removed, together with the enlarged gland. During this portion of the operation the constricted knuckles of gut, which when first brought into view had been black, crepitant and distinctly offensive in odor, had rested on the upper portion of the thigh of the patient, covered with hot carbolized towels, and had gradually recovered their normal color and consistence to such a degree that I resolved to return them to the abdomen. After doing this the upper portion of the sac and its neck were with considerable difficulty separated from the surrounding structures, careful dissection with the scalpel and the finger being required. The sac was then drawn strongly downward from the internal ring, and was tied with a stout silk ligature half an inch above the upper line of the incision which had been made into it. The ends of this were left long and threaded through stout curved needles. One of the threads was then carried up the canal, through one of the walls of the internal ring, and through the abdominal wall above and external to the internal ring, and the other carried through the opposite edge of the internal ring and through the abdominal wall, the skin being pulled aside in both cases, so that the sutures passed only through the fascial and muscular layers. These threads were then brought together and tightly knotted, thus fixing the stump of the sac in the internal ring, and at the same time almost completely closing the latter. The operation up to this point was practically that recommended by Mr. Barker, of University College, London.

Attention being then directed to the fundus of the sac, which remained *in situ*, it was found greatly thickened and tightly adherent to every portion of the surrounding tissues. The patient's condition not being good and there being no special advantage, as it appeared to me, in the removal of the fundus, this was left undisturbed. The tissues on either side were then stitched together by catgut sutures, excluding the skin. The wound then presented through its upper two-thirds two broad fleshy walls which seemed admirably adapted for rapid union.

Up to this point I had thought of concluding the operation after the method of Dr. Charles McBurney, of New York, leaving the wound open after sewing together on each side the various layers forming the abdominal wall, excluding, of course, the transversalis fascia and the peritoneum, and then packing it with iodoform gauze; but, as I have stated, the prospect of obtaining rapid union through the upper two-thirds then appeared to me so good that I brought all that portion together by closely applied interrupted catgut stitches, having first laid in the depths of the wound some strands of chromicized catgut to provide for drainage. The lower third, communicating with the remains of the fundus of the sac, was left open, and was filled with long strips of iodoform gauze.

Full antiseptic measures were employed throughout the entire operation, which was then completed by the application of antiseptic dressings, consisting of wet sublimate gauze, sublimate cotton and an antiseptic spica bandage. The patient recovered without a bad symptom. He was extremely restless at first, and a few drops of pus formed and discharged at the upper angle of the wound, which everywhere else united by first intention throughout its entire extent. The cavity at the bottom of the sac rapidly disappeared through contraction of the dartos and the scrotal tissues and obliteration of the sac by granulation. The patient had several large movements of the bowels within the first three days, and has never since had the least abdominal distention, swelling or tenderness. The temperature and pulse have been normal since forty-eight hours after the operation.

The patient is now, ten weeks after the operation, up and about, with a solid linear cicatrix, wearing no truss or other support, the use of which after operations for the radical cure of hernia I believe to be unphilosophical. With the exception of the scar, there is but a trifling difference between the two sides of his abdomen in the region of the hernia; and although it is too early to add the case to the list of successful operations, there is, as yet, certainly no return of the hernia. There is, however, a spot above the middle of Poupart's ligament at which the abdominal walls seem thinned and weak, and it may be that a hernial protrusion will make its appearance after he resumes his work.

It is, as yet, uncertain whether the statement of Leisrink, that the radical operation is less apt to be followed by relapses in cases of strangulated hernia than when done in other cases not complicated by strangulation, can be accepted as proven.

Weir's statistics, on the contrary, show that in operations on free or non-strangulated hernias relapses occur in 47 per cent., while in 138 cases of strangulated hernia operated on by Andaregg, Macewen and Reichel, 49 per cent. relapsed. The interesting question, therefore, whether strangulation,

or the inflammation and thickening of the sac which accompanies it, increases, as may be possible, the chances of rapid and thorough adhesion of the structures about the inguinal canal, and should, therefore, increase correspondingly the probability of securing a permanent result, must be regarded as yet undecided. Setting aside the factor of strangulation, the present case can hardly be considered a favorable one. The extensive adhesions, the age of the patient, the size of the tumor, the great distention of the abdominal rings, the involvement of the omentum, the doubtful condition of the gut and the extensive secreting surface which it was necessary to leave behind were distinctly unfavorable elements. The conclusion of the distinguished French surgeon, M. Socin, which was announced at the recent French Surgical Congress, and concurred in by all present, that "the chances are better in proportion to the youth of the patient, the smallness of the hernia and the shortness of duration," is that of all practical surgeons, and, as I have remarked, all these factors are absent in this case. Another opinion also expressed by him on the same occasion is at the present time as widely accepted, viz., that the operation for radical cure is the necessary complement of all kelotomies performed for strangulation, excepting only the cases in which the intestine cannot or should not be reduced.

In regard to the technique of the operation, the most important points to be noted are the treatment of the sac, the treatment of the rings and the edges of the canal and the employment or non-employment of pressure by truss or otherwise. Macewen's operation, in which the whole sac is retained, and after careful dissection folded upon itself by means of a ligature passed through it longitudinally, and is then stitched to the internal abdominal ring, has always seemed to me to have two objections: 1st, it requires a complete dissection of the entire sac, often a tedious procedure, and one which prolongs the operation at a period when it is desirable to complete it as soon as possible; 2d, although it is said to form a plug or buttress for the internal abdominal ring, it certainly leaves that portion or pouch of peritoneum more or less distinct, and to that extent favors a return of the hernia.

In the operation of excision of the sac, if strong traction be made at the time of applying the ligature, all trace of the hernial pouch of peritoneum may at once be obliterated, as may be readily demonstrated on the cadaver. A comparatively smooth surface is left with the minimum amount of cicatricial tissue. Macewen's plug consists largely of inflammatory lymph which unites the folds or layers of the sac, and finally becomes scar tissue, which always and everywhere throughout the body tends to break down and become absorbed under pressure. For these reasons I believe excision of the sac to be preferable. Twisting of the sac, as recommended by Mr. Stokes, is open to the objections to which attention has been called by Dr. McBurney, that a portion of adherent intestine might be drawn into the twisted canal, or a rupture of the peritoneum might result. To counterbalance these dangers I see no advantage whatever to be derived from this plan over that of excision and ligature of the sac. As to the treatment of the rings and edges of the canal, I believe that the bringing together of the separate layers on either side of the canal, with the idea of securing the union of their edges, is less efficient than the plan which I have above described.

The broad, fresh surface which is thereby obtained offers a greater probability of rapid union by adhesive inflammation than when the thin layers of fascia and muscle are stitched separately. Then, too, if union should not be obtained by this plan, the wound is left in good condition for the employment of McBurney's method and can be readily packed with iodoform gauze at any period after the operation. As to the subsequent employment of the truss, the same principle which I have mentioned as offering an argument against Macewen's method—namely, the ready disappearance of cicatricial tissue under pressure—seems to me to constitute a valid objection. The whole operation may now be said to be on trial before the profession, and each case has a distinct value, and should be carefully recorded and considered.

In those hernias in which the vaginal process of the peritoneum remains patulous and the hernia lies in contact with and surrounds a testicle, the problem of effecting a radical cure is manifestly complicated. The ordinary plans are inapplicable, as the sac of the hernia surrounding the cord and testicle can neither be folded up after Macewen's plan, nor ligated and excised. It is directed in these cases (Barker, *Operative Surgery*) to divide the sac in the middle and then close up the lower part by a few stitches, so that it may form a tunica vaginalis. The upper portion is then to be sealed up posteriorly, allowing the cord to escape behind it, after which it is closed up by stitching, and may then be treated by any of the ordinary methods. It has always appeared to me that this must necessarily leave a weak point in the neighborhood of the cord and that the effacement of the hernial pouch must be more or less incomplete.

For these reasons in a certain proportion of cases, especially those in which a congenital hernia is complicated with a retained testicle, it seems justifiable to sacrifice the latter organ, particularly, of course, if it be atrophied. The following case will illustrate this point:

C. B., a man, twenty years of age, was admitted to the German Hospital on the evening of May 5th,

suffering with strangulated, oblique, complete inguinal hernia of the right side. With the exception of the knuckle of gut which it contained, the scrotum on this side was empty, and it appeared that when the hernia was reduced the right testicle could be felt in the inguinal canal. It frequently gave him great pain and distress, and the hernia was very difficult to retain on account of the presence of the testicle, the truss exciting swelling and inflammation; for the same reason the attacks of strangulation had been frequent. On this occasion the pain was agonizing and unbearable, and both the patient and his family, who accompanied him, agreed that the prevention of other recurrences was worth any risk. Herniotomy being performed in the usual manner, the small, immature testicle was discovered lying in the inguinal canal near the external abdominal ring and held in place by bands of recent inflammatory lymph. The sac, *i. e.*, the tunica vaginalis, contained a large quantity of fluid and ten or fifteen inches of much congested intestine. The stricture, which was at the internal ring, was divided and the gut easily reduced. On account of the history which the patient had given, and for the reasons stated above, the cord was then ligated as high as possible, the stump returned to the abdomen, and the remaining portion, together with the testicle, removed. This allowed the upper portion of the sac to be pulled strongly down and ligated, after which the remainder was easily dissected out with the finger, as in cases of castration. Catgut drainage was used, the wound brought together after the method I have described above, the layers in each wall of the wound being first stitched to each other, and the whole wound approximated afterward. Union by first intention under one dressing followed, and the patient was left with a firm cicatrix, and at the present time, five weeks after the operation, without the slightest remains of the hernial tumor.

NOTE ON THE ACTION OF DIGESTIVE FLUIDS ON OIL.

BY H. W. WILEY, M.D.,
OF WASHINGTON, D. C.

IN a paper by Dr. D. W. Prentiss (THE MEDICAL NEWS of May 12, 1888, p. 518), attention was called to the occurrence of so-called gall-stones in the dejecta after the exhibition of olive or cotton-seed oil, and the substance of a preliminary study which I had made of the compositions of these bodies was given. At Dr. Prentiss's request I have since collected additional data referring to this matter.

The action of the gastric juice on fat seems to be confined to separating therefrom all connective and enclosing tissue and thus setting the fat free. It is found in the stomach in large globules and passes the pylorus unchanged.

The pure intestinal juice seems to exert no action whatever on fats, and these substances are said by Busch to appear in the feces unchanged when subjected to the action of the intestinal excretions alone.

Flint says that, while the action of the pancreatic juice in emulsifying fat is undisputed, there is no evidence that in normal digestion there is ever any saponification. The fats found in the thoracic duct are always neutral, and do not contain any free fatty acid. On the other hand, Bernard has shown that the pancreatic juice outside of the body has a distinct power of saponifying fats. Landois and Stirling, however, recognize the saponifying power of the pancreatic juice in normal digestion, but attribute the result to a fat-splitting ferment called *steapsin*.

The process of emulsification is said to go on with much greater rapidity when the fat in question contains a trace of free acid. The surface of each fat globule becomes coated with a thin film of soap, which is soon detached, carrying with it minute particles of fat. The repetition of this process secures finally a complete emulsification. Both the soap and emulsion are absorbed. The authors state further that soluble fat soaps represent only a fraction of the fats which are absorbed, the greater part of the neutral fats being absorbed in the form of an emulsion. Absorbed soaps, however, have been found in the chyle.

Buchheim, in his *Lehrbuch der Arzneimittellehre*, third edition, p. 370, says: "The pancreatic juice also possesses the property of dividing fats into fine particles, at the same time that it effects, by reason of a ferment contained therein, a partial saponification of them."

Edes (*Therapeutics and Materia Medica*, p. 287) refers to the saponification of olive oil when administered in large doses, and the excretion of semi-solid masses of soap.

What relation the saponification of fat in the intestinal canal may have to its food value I cannot say. Recent experiments of Kellner (*Zeitschrift für Physiologische Chemie*, vol. xii p. 113) show that as a food for a draught horse one part of fat is equivalent to 2.6 parts of starch. Six and a half ounces of linseed oil enabled a horse to perform 464,000 pounds more work in a day than without this food. Hoppe-Seyler (*Physiologische Chemie*, Part IV. p. 949) ascribes the power of fat food to increase the amount of work performed to its influence in diminishing the consumption of the nitrogenous tissues. Whatever the true view may be, it seems certain that we have not yet quite understood the exact processes of fat-digestion and assimilation.

Dastre, in a recent study of the action of the bile in fat digestion (*Comptes Rendus*, tome 106, p. 217), has shown that the pancreatic juice alone is not capable of digesting fats. These conclusions of Dastre have just been confirmed by the experiments of Prevost and Binet (*Comptes Rendus* of June 11, 1888, p. 1690). These investigators find that in dogs, when the bile is prevented from taking part in digestion, fat foods are voided unchanged.

By an artificial cholecysto-intestinal fistula in dogs, they caused the bile to be emptied into the intestinal canal at a point twenty-five to forty inches from the duodenum. Through all this distance the fatty matters passed, subject to the action of the pancreatic secretion alone. The dogs being killed during the progress of digestion, the chylefers were examined. There was no trace of any absorption of the fat until after the mingling of the bile with the contents of the canal. Whence Dastre concludes that the presence of both bile and pancreatic fluid is necessary to the digestion of fats.

Dr. Prentiss, of this city, administered to a patient a large dose (a pint) of cotton-seed oil. In the dejecta were found large numbers of moderately hard ovoid bodies, which the patient thought were gall-stones. They were brought to Dr. Prentiss, who preserved them in a stoppered bottle and sent them to me for examination. On reaching me the whole had melted to a viscous mass resembling soft soap. On examination it proved to be a true soap, a mixture of soap and free fatty acids, easily soluble in alcohol, yielding fatty acids insoluble in water on treatment with an acid. After saturation with hydrochloric acid the chlorides of the alkalies were separated from the fatty acids by filtration, evaporated to dryness, ignited to low redness to drive off any ammonia and to destroy organic matter; the residual chlorides were dissolved in water, filtered through a small filter, evaporated nearly to dryness, dissolved in alcohol and treated with platinic chloride. A distinct precipitate of potassio-platinic chloride was formed, showing a trace of potassium. The chief part of the alkali, however, was soda, with, possibly, some calcium. This is an interesting case, showing the complete saponification or decomposition of a large quantity of oil by the pancreatic juice and bile, perhaps with the aid of a fat-splitting ferment, and the passage of the greater quantity of soap and acids thereby formed unabsorbed through the alimentary canal.

Since the complete saponification of such an amount of oil would require more alkali than is normally found in the intestinal canal, it seems probable that the oil may be split up in the canal without complete saponification. I have, unfortunately, taken all the sample sent me for the first examination and therefore will not be able to decide this point until opportunity for another analysis is presented.

The occurrence of semi-solid masses in the feces has been noted by many writers, but they have usually been called gall-stones. The *Therapeutic Gazette* for May, 1888, reports a case of this kind, but evidently without believing it true. As has already been noted, Dr. Edes has properly named these excretions, but informs me that he does not know of any analysis of them having been made.

Mojon (*Revue Médicale*, 1844, quoted in Thudichum's *Treatise on Gall-stones*, p. 199) says, "concretions of solid fat occur in the feces after the use of sweet oil;" but in this he is evidently mistaken. Sweet oil could not produce a concretion of solid fat without undergoing a more profound change than saponification. These concretions were, doubtless, masses of soap, such as I have described above. Thudichum (*Treatise on Gall-stones*, p. 135) describes certain biliary calculi which were composed largely of calcium soaps. The hardness and crystalline structure of these stones, however, would prevent them from being confounded with the masses of soap and acids forming the subject of this study. In the feces of dogs, Hoppe-Seyler (*Physiologische Chemie*, p. 337) has found calcium soaps of stearin, palmitin and olein. The feces are exhausted with alcohol and ether, and the residue treated with hydrochloric acid and a mixture of alcohol and ether. Wegscheider (*op. cit.*) has found these calcium soaps, also, in the feces of healthy children who were nourished exclusively by mother's milk.

I desire to thank Drs. Prentiss, Edes and Lee for favors extended in the preparation of this note.

WASHINGTON, D. C., July 3, 1888

TWO CASES OF BASE-BALL PITCHER'S ARM.

BY A. H. P. LEUF, M.D.,
OF THE UNIVERSITY OF PENNSYLVANIA.

As a supplement to my paper on "Base-ball Pitcher's Arm" that appeared in THE MEDICAL NEWS of July 15, 1887, I would offer the following cases of two noted pitchers treated by me in the middle of last season (1887).

CASE I.—Mr. W., male, single, about twenty-five years of age, average height and weight, and inclined to be thin. Had never worn any elastic bands on his pitching arm. Was never troubled with a bad arm until last year. He seriously intends to "lay off" for one month, because of a very sore arm. Has pain under the scapula (anterior border) and anterior fibres of the deltoid. There is marked atrophy of the teres minor. The deltoid seems not atrophied. Pitching the out-curve pains him. Has been steadily getting worse. Is taking another physician's medicine for indigestion and diarrhœa.

Treatment.—This consisted in regular morning and afternoon exercise, for an hour each time. He was instructed to surround the shoulder with towels wrung out of hot water, and applied as hot as could be borne, both after and between exercises, so as to make at least four applications a day. All shower and cold baths were interdicted. A warm bath was to be taken after each game. Galvanism was applied to the teres minor and anterior fibres of the deltoid, so as to redden the skin and cause marked contraction on interruption and reversal of the current. Reversal of the current caused but slightly more contraction than simple interruption.

Prognosis.—Keep up work, and pitch in game in

a few days, but continue treatment for four or six weeks at least. Recovery ought to be complete.

Second visit, three days later. No pain whatever during practice. Highly elated. Will pitch in a game on Monday or Tuesday. Continued treatment.

Third visit, four days later. Pitched yesterday. Arm felt "fine." "Not the slightest ache or pain." Says he could have pitched another full nine-inning game. Arm felt a little stiff and swollen this morning; after galvanism this entirely disappeared. Pitches again to-morrow. In yesterday's game he pitched against the C—— team, with M—— in the box; only seven actual hits were made off him, and he gave two men bases on balls; twelve actual hits were made off M——. To-day's paper says of the patient: "W—— pitched a remarkable game." He won by a score of 3 to 2.

Next day he returned for galvanism, and felt so well that he did not think it necessary to call again. In a few days he left the city with his club, and while in the west, a few days later, he pitched, on two successive days, against one of the greatest ball clubs ever organized, and won both games on the opponent's grounds, a very remarkable feat of endurance and skill. He suffered no bad effects, and during the balance of the season his arm never troubled him again.

Case II.—Mr. A., male, married, æt. twenty-nine years, tall, and of fine physique. Muscles of the right arm remarkably developed and very firm. Wears an elastic elbow-band, and has done so for a couple of seasons. Extension at the elbow is incomplete and due to slight contraction of the brachialis anticus and biceps, and osseous enlargement of the lower end of the humerus and upper ends of the radius and ulna. Was able to extend both arms equally well at first, but the pitching arm began not to admit of full extension. Was injured at Cleveland while pitching, so that he had to stop at once. Since then he has been under medical treatment, but was getting worse all the time. At the present time he cannot dress or undress unaided. Had to help him off with his coat. Can hardly bend elbow. Has it slightly flexed at an angle of about 150°. Has severe pain and considerable swelling on both sides of the olecranon and on either side of the triceps tendon just above, being most marked on the inner side. The out-curve is the most painful by far Flexion at the elbow causes pain along the distribution of the ulnar nerve, which is very tender behind the internal condyle. There is no osseous tenderness. Says that sometimes he feels a snap at the site of the head of the radius, and that then he cannot flex his arm until it has been pulled and rotated. This seems as if it might be a subluxation of the head of the radius. Also pain in anterior fibres of the deltoid. Wants to know if he is disabled for life, and if not, if he can pitch again during this season. Estimated time for reasonable cure two weeks, or complete cure nearly two months.

Treatment.—No shower or cold bath. Warm baths after each game. Elbow dipped in hot water three or four times a day, as hot as can be endured, and kept up for about half an hour each time. Arm not to be used until after next visit. Applied galvanism, + pole at nape of neck and — pole at sore spot of elbow. Current strong enough to redden skin and cause marked muscle contraction during interruption of current. Also applied — pole to the deltoid (anterior fibres). Both were then applied to the elbow, allowing the current to pass through the joint and surrounding structures from before backward. Felt comparatively little pain after the galvanism, even in efforts at pitching. To return in five days.

Second visit, five days later. Very much improved. Flexes and extends arm readily, and with little pain. Motion of moderately swift throwing or pitching gives very little inconvenience. Continued treatment and advised beginning to practise moderately every day, in the morning and afternoon, for about one hour each time.

Third visit, two days later. Still more improved. After first practice (in afternoon) arm was very painful, not having used it for about two weeks. After second practice (in morning of next day) it was not nearly so painful. After the third practice (the afternoon of the same day as the second) he had almost no pain. Had a little this noon (next day) in the vicinity of the olecranon, but was free from it after galvanism. Perhaps will pitch in a game day after to-morrow.

Fourth visit, one week later. Has pitched for about one hour, every morning and afternoon, since the last visit, and never had the slightest pain or inconvenience until to-day. While pitching this afternoon he suddenly had a slight pain at the tip of the olecranon in pitching the in-curve. Stopped at once. Applied thirty cells of the Barrett chloride of silver battery until the skin was red, and broke and reversed the current repeatedly. Showed him how to pitch an overhead in-curve and out-curve without straining his elbow and radio-ulnar joints. He cannot touch his right (pitching) shoulder with the tips of the fingers of the same side, though he could before he became a pitcher, and can do so on the other side. Pitched in a game next day without much trouble.

I have purposely run the risk of being tiresome in the recital of these cases by making almost verbatim copies from my histories. These two were selected because very bad, and one quite intractable. The first case was remarkable for its prompt response to treatment, and the permanency of the cure, for at no time during the season did his arm trouble him. Case II. was seen by me again several times during the season, and hardly any trouble remained, at least not enough to prevent first class pitching. I have seen him this winter (in February, 1888), and find his arm in better condition, as he tells me, than ever before.

These cases show the quick response of such injuries to good treatment, and the certainty with which they get worse under wrong treatment. It is not only necessary in such troubles to use galvanism properly and give good advice, but it is necessary

(as I did in Case II.) actually to see them pitch, and study their delivery so that advice may be given as to change of delivery, thus enabling them to rest the affected parts while they still remain on duty and draw pay. This is very important when we recollect that the "laying off" of a good pitcher for a couple of weeks means a loss to him of from $50 to $100, or even more.

129 SOUTH THIRTY-SIXTH STREET.

CHOREA OF PREGNANCY AND OF THE AGED.

BY C. L. DODGE, M.D.,
OF KINGSTON, N. Y.

A FORM of chorea occasionally occurs during pregnancy. It is extremely rare. Sinkler (Pepper's *System of Medicine*) gives sixty-six cases as the total number recorded to date. Inasmuch as chorea is a disease of childhood, the large majority of cases occurring between the ages of five and fifteen years, we should not expect to meet with it frequently in adults. The chorea of pregnancy is said to be a very serious and often fatal affection, and almost beyond the power of remedies to control.

CASE.—Mrs. T., twenty-three years of age. First saw her May 3, 1886; about eight months advanced in her third pregnancy; she was a large, healthy-looking woman, weighing one hundred and fifty pounds; no history of rheumatism; never had chorea when a child. About two months before, she first noticed symptoms of muscular weakness of the left arm and foot, soon followed by inability to control the movements of the left hand; this grew steadily worse, till she was finally obliged to fasten her arm to her side, to prevent injury to the hand, as she was utterly unable to control its movements. Mental condition good, but speech somewhat affected. The bromides, arsenic and iodide of iron were tried in vain, absolutely no improvement taking place. At eight and a half months, she was taken with convulsions. I continued the bromides; also gave morphia and chloroform, notwithstanding which they recurred at intervals for twenty-four four hours. They seemed to me to be epileptiform in character, so I did not at first resort to venesection; but the next day, after consultation, I decided to bleed her. After removing about twenty four ounces of blood, we tied up her arm, and she appeared much better, was able to converse intelligibly and seemed perfectly rational. She had no more *convulsions* afterward; she would have peculiar nervous "spells," as her friends termed them, but no more fits. The chorea, however, remained fully as bad as ever. It persisted, for nearly three weeks after confinement, to such an extent that it was necessary to bind her arm to her side while she nursed the baby, for fear of injuring it. By the end of the month, she began to show signs of improvement, and, in less than two months from the time of her accouchement, she had entirely regained the use of her hand, and, to this time, has had no return of the trouble.

The family history here is interesting. Her mother has been subject to rheumatism all her life; she also had chorea during her pregnancy and with *this child*, which was *her third* pregnancy. The patient has an older sister who has epilepsy. She cannot recall any particular fright during her pregnancy, but says she was obliged to stay alone at nights a great deal, her husband being away from home, and she would get very nervous at such times and often lie awake most of the night.

Primiparæ are said to be most frequently affected; indeed, the four cases recorded by Sinkler and referred to by Osler (THE MEDICAL NEWS, October 22, 1887) were all primiparæ. The mental symptoms are frequently severe, and the mortality high, ranging, according to Osler, from twelve to thirty per cent. Out of sixty-six recorded cases, chorea occurred previously in fourteen. Rheumatism and fright seem to act as exciting causes in a number of cases (Sinkler).

The causation of the chorea of pregnancy, so far as known at present, according to Wood (*Nervous Diseases*), is summed up as follows:

"There are, usually, a predisposition to chorea, inherited or acquired, inanition of the nervous system incident to the hydræmic state of the blood during pregnancy, and various potential peripheral irritations, especially in connection with the sexual organs. The most rational explanation of the chorea of pregnancy is that it varies in its immediate pathology, the pregnancy simply producing a condition of the nervous system which predisposes it to be thrown into an active chorea by various exciting causes."

Senile chorea is even more uncommon. Sinkler has reported two cases, which, according to Osler, are the only instances recorded in this country. Saundby has collected but twelve cases abroad, the ages ranging from fifty to eighty-six, six of each sex (Osler, MEDICAL NEWS, October 15, 1887). He also adds that it seems to be an intractable affection, similar in many respects to the juvenile form, not often associated with rheumatism, and the subjects of it are very frequently dements. Hammond affirms (*Diseases of the Nervous System*, 8th ed., p. 739) that "in those cases reported by authors, of the affection originating very late in life, we have every reason to conclude that they were instances of organic lesions of the brain or spinal cord—probably sclerosis—giving rise to rhythmical movements or paralytic tremor." The following, I think, will be admitted to be a case of chorea, pure and simple.

Mr. D. First saw him September 22, 1883, and he was then seventy-five years of age; his health had always been good; was rarely ever sick; no history of rheumatism or nervous affection of any kind when a child; had always worked hard on a farm; one year before, he began to notice some muscular weakness and want of control over the left hand, and, soon after, of the left foot also; later, his speech became affected, with the muscles of the left side of

his face, causing the peculiar and well-known grimaces characteristic of chorea. His general health remained unaffected; appetite good; ate heartily, slept well, etc. In October, 1886, he was attacked with hemiplegia of the *right* side, which rendered him entirely helpless; his speech became so indistinct as to be unintelligible, with complete paralysis of the right side. The choreic movements of the left side still continue, however, up to this time, as he is still living.

The family history is negative, but his children and granchildren are affected with various nervous troubles. His daughter had chorea when a child, but recovered. His granddaughter (daughter of the one just mentioned) had hystero-epilepsy for two years, but has apparently recovered, after treatment with chloride of gold and sodium. His grandson (brother of the last mentioned) has slight choreic spasms of the right side of the face. The children and grandchildren were all relieved by treatment, but the old gentleman never improved in the slightest under any kind of treatment whatever.

This, to my mind, goes far to prove an hereditary tendency or predisposition, requiring only some special exciting cause to develop the malady.

MEDICAL PROGRESS.

The Treatment of Summer Complaint at the Thomas Wilson Sanitarium, Baltimore.—In acute diarrhœa, with vomiting of milk, the child is at once taken from the breast or bottle, and no food except beef tea is given to it for twenty-four hours. Small doses of calomel—$\frac{1}{12}$ to $\frac{1}{8}$ grain—are administered hourly for a day or two, to quiet the stomach and to excite the secretion of the liver. At the end of twenty-four hours *sterilized milk* is given. If the vomiting returns, the milk is stopped and beef tea is resumed for twenty-four hours, when milk is once more given.

No artificial foods are used in the Sanitarium. Irrigation of the lower bowel is practised two or three times a day, if it does good. In chronic cases, resorcin, grs. ij, with tr. opii deodorata, gt. ½, is given every two or four hours. When vomiting proceeds from nervousness, sodii bromidum, grs. ij, and chloral hydrate, gr. j, are administered every two or four hours to a child of six months. This same prescription is used for sleeplessness. As a rule, no further medication is needed.

Dr. Brooker considers the *sterilization of the milk* a great improvement, likely to do away with wet-nursing and artificial foods. Milk as it flows from the breast is free from microscopic germs. Between the time when the cow's milk leaves the udder and the time when the baby drinks it various minute organisms may fall into it, which, either before or after the child takes it, produce changes in the milk which cause disorder of the digestive organs of the child.

By *sterilization* we either destroy these organisms or check their growth. The apparatus for sterilization is a covered tin bucket, 10 inches in height by 8 in diameter, and a wire basket, made by Dufur & Co., of Baltimore, large enough to hold six or eight nursing bottles. In the bucket, filled to the depth of one inch with hydrant water, is placed the wire basket with the nursing bottles, each of them containing a suitable amount of milk and stopped with a wad of cotton batting. The bucket is then covered and placed on a gas stove, and the water is boiled for half an hour, the milk, bottles and stoppers becoming sterilized by the heat. After cooling, the basket of bottles is kept in a cool place, and one by one, as needed, the bottles are removed, the stoppers taken out and a disinfected nipple is attached for nursing. Milk enough to supply one baby for twelve hours is thus prepared at once, and if kept in a cool place—even without ice, it will remain sweet and wholesome until used. The whole apparatus, including bottles, costs a little more than a dollar.

It is stated by Dr. Brooker that when the infant's bowels have once been cleared of ill-digested milk by change to beef tea and by irrigation, the use of sterilized cow's milk, properly diluted, is followed immediately by great improvement in the health of the infant, as great as when it returns to the breast of its mother.

For irrigation of the bowels a fountain syringe full of tepid hydrant water is connected with a soft rubber catheter about fourteen inches long, and this catheter, oiled, is passed gently to its full length into the rectum and descending colon, the water—a gallon or more—being allowed to flow into the bowel and out again by the side of the catheter. This irrigation is painless and often aids greatly in recovery, especially in severe cases resembling cholera infantum.—*Maryland Medical Journal*, July 14, 1888.

The Supposed Transition of Benign Growths of the Larynx into Malignant.—It has been suggested that benign growths of the larynx, as a result of intra-laryngeal operations for their removal, are liable to become transformed into malignant tumors. This suggestion, if proved to be well founded, would do much to show that von Bruns's introduction of the intra-laryngeal operation for tumors was not the great improvement it has been held to be; but, on the contrary, a very mischievous procedure. The plan of collective investigation has been employed by Dr. Semon, the editor of the *Internationales Centralblatt für Laryngologie*, etc., to throw light upon this subject, and in the July number of that journal the results of the inquiry are briefly given. These are so important that the profession ought at once to be made fully acquainted with them.

Returns have been furnished by 107 observers, who have together recorded 10,747 cases of benign growths in the larynx and 1550 cases of malignant tumors. Of these 10,747 cases of benign growths, 8216 have been submitted to intra-laryngeal operation, and among this number there are 3382 cases of papilloma. An apparent transformation from benign into malignant growths has been noticed in thirty-two instances. Each one of these cases must be submitted to a very careful criticism, but, apart from that, as many as sixteen of the number are by those who record them marked as "doubtful," and they cannot therefore be used. It is quite open to question whether the remaining sixteen cases do not include examples of "mixed" growths, and it is noteworthy that the tables include twelve cases not submitted to intra-laryngeal operation, in which a similar change in

the nature of the growth was thought to be noticed. But putting aside this view altogether, we are met with this supposed change in one case out of every 513 cases thus treated. It must be at once admitted that if the operation had any appreciable influence in modifying the nature of a neoplasm, the proportion of cases in which it would be observed would be much greater than this.

Considering the enormous advantages the intra-laryngeal method of operating possesses, it is a matter of considerable satisfaction that it is thus conclusively shown not to be attended with the grave danger that has been suggested in some quarters.—*Lancet*, July 7, 1888.

Salicylate of Sodium in Acute Articular Rheumatism.—In what large doses salicylate of sodium can be given in acute articular rheumatism is well shown by the experience of PROF. v. JAKSCH. "In a severe case of articular rheumatism, in an otherwise healthy individual," he says, in the *Wiener medizin. Pr.*, No. 1, 1888, "I give at least 150 grains, even 225, 300 to 360 grains of salicylate of sodium in the first twenty-four hours of treatment. Should toxic symptoms arise—a rare occurrence, I do not stop the remedy, but merely reduce the dose, so that, for instance, instead of 15 grains but 8, or even 4, are hourly given; I do not consider it judicious to stop the remedy entirely. As a result of this treatment, as a rule, the main symptoms disappear after a few hours, the patients sweat profusely and feel comfortably. In the second twenty-four hours, the salicylate is and must be continued, but in smaller doses; if 300 grains have been given in the first twenty-four hours, 270 or 240 grains are now given, whether the patient show toxic symptoms or not; even then it is injudicious to at once discontinue the salicylic medication; is this done, a relapse may be hourly awaited; to prevent such relapse, the patient must continue the salicylic treatment at least eight days, the quantity of the drug used being day by day diminished."

Should no marked improvement occur after the first twenty-four hours, the case is one of those not infrequent cases of acute articular rheumatism which resist treatment with the salicylic preparations. In these, the benzoate of sodium, up to 450 grains a day, is particularly recommended.—*Deutsche medizin. Wochenschr.*, June 14, 1888.

Agaricin for the Sweats of Phthisis.—LAUSCHMANN (*Pest. med. Chir. Pr.*, 1887, Bd. 4) recommends the following formula:

R.—Agaricin. . . . . gr. j.
Pulv. ipecac. et opii . . . gr. xv.
Gum Arabic,
Pulv. alth. . . . . āā gr. viij.—M.
Ft. Pil. No. xv.
S.—One or two pills at night.
—*Deutsche med. Woch.*, July 5, 1888.

The Relations of the Subcortical Centres to Epileptic Seizures.—ZIEHEN, of Jena (Verslg. d. Südw.-deutsch. Neurologen u. Psychiater), has found that mechanical irritation of the corpus striatum, of the middle and posterior portions of the thalamus opticus and of the anterior pair of the corpora quadrigemina gives rise to energetic movements of locomotion, while irritation of the posterior pair of the corpora quadrigemina occasions tetanic convulsions. He, therefore, considers the centres last mentioned as the source of the tonic convulsions of epilepsy.—*Wiener medizin. Pr.*, July 1, 1888.

Sulphonal.—Two articles on this subject appear in a recent number of the *Berliner med. Wochenschr.* (June 18th), one by Dr. H. Rosin, of Breslau; the other by Dr. C. Oestreicher, of Berlin.

DR. ROSIN tried sulphonal on eighty-two patients, besides others. In doses of two grammes (half a drachm) it was found almost invariably to have a decided hypnotic effect, without any disturbing symptoms, even when cardiac derangement was present. Such a dose Dr. Rosin considers equal to one-sixth or one-seventh of a grain of morphine, but the latter was found more efficient when the insomnia was due to cough or pain. A dose of four grammes (one drachm) produced a sleep lasting three or four hours in the daytime, but much longer at night; but the sleep after the dose always left a feeling of heaviness behind it. Dr. Rosin, who sticks to his text, concludes thus: "On the whole, sulphonal in doses of two grammes (half a drachm) is as certain in its effects as morphine or chloral, and in cases of simple insomnia may be recommended in doses of double that strength, on account of its freedom from after-effects."

DR. OESTREICHER observed the effects of sulphonal on fifty patients with nervous diseases, besides some who were phthisical, and concludes that in moderate doses—that is, two grammes (half a drachm)—this drug is a non-injurious hypnotic. Respiration, pulse and kidney-secretion were unaffected; the effects of persistent use are, of course, unknown at present. It is best given in capsules or tabloids, from its insolubility in water. Oestreicher finds it without smell or taste; Rosin states that it has a slightly bitter taste. Sleep sets in more slowly than after chloral or morphine, in corresponding doses, but lasts longer. The editor of the *Berliner klin. Wochenschr.* confirms the above from observations of his own.—*British Medical Journal*, July 7, 1888.

Quebracho for Dyspnœa.—From a study of seven cases with asthmatic symptoms and dyspnœa in various affections, as in ascites, bronchial catarrh, emphysema and tuberculosis, WALTER P. ELLIS recommends quebracho in the treatment of dyspnœa. He uses both the solid and the fluid extract of Aspidosperma quebracho (as reported in the *Therap. Monatsh.*), and states that the remedy is the more effective the severer the attack. It not only checks the paroxysm, but is equally prophylactic for months. When the dyspnœa occurs on exertion and interferes with the occupation of the patient, the prophylactic efficacy of the drug exceeds the anticipations of doctor and patient. At the beginning or, when possible, shortly before the beginning of the seizure, or upon contemplated exertion which is known to cause seizures, Ellis gives a grain and a half to two grains of the solid extract or a teaspoonful of the fluid extract, repeated at intervals of an hour, as required. He considers plausible Penzoldt's hypothesis that, through the influence of the remedy, the blood is able to take up more acid than usual and thus to satiate the intense demand.—*Wiener medizin. Pr.*, June 10, 1888.

The Topical Use of Camphoric Acid.—REICHERT has, since a year and a half, successfully used camphoric acid for chronic affections of the mucous membrane of the respiratory tract, the mouth, the bronchial tubes and of the skin. This acid is a product of the action of nitric acid upon camphor, is soluble slightly in water, freely in alcohol and ether. It is astringent and antiseptic. One-quarter to two per cent. solutions are recommended in acute angina faucium (not in diphtheria), in acute and subacute pharyngo-laryngitis and tracheitis. Inhalations of one to two per cent. solutions are less useful, but satisfactory. Acute coryza is allayed or moderated by a 1 to 500 solution in douche, or by two to four per cent. application with a brush. In chronic bronchitis and bronchiectasis camphoric acid acts as an expectorant and disinfectant. Tuberculous sores heal in six to ten weeks with a two to six per cent. solution.—*Münchener medizin. Wochenschr.*, June 12, 1888.

The Relation of Puerperal Insanity to Puerperal Infection.—TH. HANSEN, of Copenhagen, has published an interesting study (*Centralbl. f. Gynäk.*, No. 20), the object of which is to demonstrate that puerperal infection, to which most modern authors ascribe only an occasional or predisposing influence, has a real causal relation in the production of puerperal psychoses.

While assistant physician, partly in a neurological department, partly in the maternity, Hansen collected 49 cases of puerperal psychoses, of which 21 were under his own observation. Of the 49, not less than 42 showed signs of puerperal infection; of the latter number not less than 12 were fatal. These 42 are grouped by Hansen as "infection psychoses," the features of which are acute hallucinatory confusion, followed by restlessness and a feeling of fear, passing into a condition of stupidity or depression, in which the first stage exacerbates. Among the 7 cases in which puerperal infection could not be proven 2 were of eclampsia with hallucinatory confusion of short duration; the other 5 were psychoses of a different kind.—*Wiener medizin. Pr.*, June 10, 1888.

Lanolin and its Imitations.—German medical literature contains frequent testimonials, from clinical observers, of the extended uses of lanolin as an unguent basis in the treatment of skin diseases, the therapeutic application of inunctions to the treatment of constitutional diseases, as an obstetric application in the treatment of wounds and cuts, and cosmetically in the prevention of sunburn and freckling, and even "the prevention of wrinkles." Professor Oscar Liebreich's most valuable and original addition to our storehouse of the therapeutic resources is, however, subject to the usual drawback which attends the introduction of any novel and useful substance, by the occasional substitution of imperfect imitations and inferior products simulating lanolin, at least in title, which produce deleterious effects.

DR. G. MEYER, of Berlin, reports to the following effect in the *Deutsche med. Wochenschr.*, No. 19, 1888. A man, aged thirty-eight, had a hard chancre in 1875, and was treated in the Charité Hospital, Berlin, and elsewhere, for relapses, during the next five years. In June of last year he suffered from hoarseness and swelling of the testicles. Amongst other treatment, the following ointment was applied to the testicles: Pot. iodid., 1 gramme (15 grains); lanolin, 10 grammes (150 grains). The word "lanolin" was written without any affix. Severe acute dermatitis of the scrotum followed, with great swelling, redness and burning heat of the skin. The penis participated. The man could not walk about, and, therefore, left off work. The inflammation, he said, set in after the fourth infriction. The general health was not affected; the penis, as above said, shared in the inflammation, which affected both sides of the scrotum. Epididymitis was excluded accordingly, and suspicion rested on the ointment. More of this was ordered, as before, for examination only, and it smelt "acid and rancid." The skin remained like thick leather for some time. An ointment of one part of potassium iodide in ten parts of lanolin puriss. (Liebreich) was then rubbed in by Dr. Meyer himself. The skin was distinctly thinner two days afterward, without any trace of irritation by the ointment. The previous inflammation was due, there is no doubt, to the rancid lanolin used, for all sorts of lanolin, except Liebreich's, contain several fatty acids. The percentages of these in various samples of lanolin are given in the *Deutsche med. Wochenschr.*, No. 28, 1886, as 33, 26, 17, 16, 16; in Jaffé and Darmstaedter's lanolin, 0.5 to 1.—*British Medical Journal*, July 7, 1888.

Encephalic Asymbolia.—Under this term, MEYNERT, before the Society of Physicians at Vienna, described one of the forms of aphasia. Objects may be seen, but the patient can make no use of the visual impression, because the recognition of the optic pictures is lost. There is a disturbance of association between the optic centre and the centre for the interpretation of visual impressions.—*Wiener medizin. Presse*, June 10, 1886.

Ichthyol in Erysipelas.—The Russians are reviving the recommendation of ichthyol for erysipelas. The remedy has been used partly as collodion (ichthyol, ether, āā 10 parts, collodion 150), partly with vaseline (equal parts), and surprising results are claimed. It is emphasized that the application extend to the neighboring healthy tissue.—*Deutsche medizin. Wochenschr.*, June 14, 1888.

Antiseptic or Aseptic Solutions for Injection or Douche.—DEMELIN, in *Revue Générale de Chirurgie et de Thérapeutique*, June 28, 1888, recommends the following weak carbolized solution (Lister's):

R—Crystallized carbolic acid . .	25	parts.
Alcohol	25	"
Distilled water	1000	"

or,

Crystallized carbolic acid . .	25	parts.
Glycerin	25	"
Distilled water	1000	"

The latter solution is better adapted to the tissues than the preceding.

Acromegalia.—FRAENTZEL, before the Verein für Innere Medizin, at Berlin, on June 4, presented a case of acromegalia in an intemperate patient with phthisis. There was enormous development of the bones of the extremities and of the face. The hands and feet were much enlarged. Fingers, toes and nails were colossal. The soft tissues of the corresponding parts were swollen and of a peculiar, doughy consistence. The nose was conspicuous for its thickness, the lips for their prominence. At the autopsy, there was narrowing of the aorta; there

was no trace of the thymus gland; the thyroid gland was normal. In this case, the acromegalia was shown to have existed since early youth, and the condition was transmitted to a daughter of the patient.—*Wiener medizin. Presse*, June 24, 1888.

A Novel Treatment of Hydrocephalus in Infants.—DR. SOMMA (*Deutsche med. Ztg.*) has, with good results, availed himself of the heat of the sun in the treatment of five cases of chronic hydrocephalus. These are his conclusions:

1. The treatment of hydrocephalus congenitus and chronicus in infants, by means of the heat of the sun, is to be preferred to all other therapeutical measures.

2. The physiologic-therapeutical efficacy of the treatment probably consists in the excessive functional activity of the local sweat glands in consequence of the powerful excitation and of the high temperature of the head, by means of which the intracranial collection of serum is absorbed. Perhaps, too, the thermic irritation stimulates the vaso-motor innervation and, in consequence, an increased activity of organic oxidation and an increased absorption of the fluid and solid intracranial elements.

3. Recovery will be most ready when there is no injury of the cerebral tissue and the nervous manifestations are exclusively the result of pressure, when the child is otherwise healthy and not reduced; and the hydrocephalus, particularly if ventricular, shall not be far advanced.

4. The treatment is as follows: The child is given to an assistant, whose head is covered; with a clear sky, the occiput is exposed to the rays of the sun, the assistant seated and immovable. In the first four or five days, the exposure may last a half hour or less; later, forty or fifty minutes. The treatment must thus be continued for a month.—*Wiener medizin. Presse*, June 10, 1888.

Biliary Calculi in Women.—MARCHAND (*Deutsche med. Wochenschr.*, 1888, No. 12) thinks the frequent occurrence of gall-stones in women due to tight lacing, and finds a causal relation for the association of fissures of the liver and gall-stones. The compression from lacing mostly affects the region of the cystic duct, causing an abnormal retention of bile, with consecutive formation of calculi.—*Fortschritte der Medizin*, June 15, 1888.

The Use of the Double Salts of Caffeine in Pulmonary Diseases.—DR. GEMPT, from a careful study of this subject, reaches the following conclusions:

1. The double salts of caffeine are indicated in acute fibrinous pneumonia, when the heart's force lessens, the arterial pressure falls, or the pulse becomes abnormally frequent or arhythmical.

2. The administration of the remedy is to be begun, if possible, before signs of collapse arise, but the indication is the more positive in case of unexpected collapse.

3. When asthenia or lesions or degeneration of the heart exist, and in the cases of infants and of old persons, the remedy is to be recommended at the beginning of the disease.

4. The proper administration of appropriate doses causes diminished frequency of pulse and respiration, rise in arterial pressure, reduction of temperature, and produces a favorable influence upon the subjective condition.

5. The action begins speedily, but is more speedy and more certain in threatening cases if the drug is injected subcutaneously.

6. In conditions of pulmonary atelectasis or hypostasis, the same indications exist.

7. The indications for the use of the sodio-salicylate of caffeine in pulmonary emphysema and asthmatic conditions is analogous to those for its use in heart diseases. —*Berlin. klin. Wochenschr.*, June 25, 1888.

Naphthol in Ozœna.—At the recent Congress of the French Society for Laryngology, RUALT recommended naphthol in the treatment of ozæna. He irrigates the nasal cavity, three or four times daily, with the following solution, to be freshly prepared before each application: To a quart of water, add a teaspoonful of a solution of equal parts of biborate of sodium and bicarbonate of sodium, and a teaspoonful of a solution of beta-naphthol, 12 parts, in alcohol (90 per cent.), 84 parts. In obstinate cases, in addition to the preceding, cotton tampons, saturated with the following, are introduced into the nares for fifteen minutes: beta-naphthol, 12 parts, tincture of quillaya 88, distilled water, 400. The advantages of this treatment are the rapid disappearance of the odor and the decided diminution in the secretion. The only objection to naphthol is a slight burning, occurring immediately after its use, but soon disappearing.—*Wiener medizin. Presse*, June 17, 1888.

Sulphonal.—SCHWALBE, of Friedrichshain, assistant to Fürbringer, from a study of the use of sulphonal in fifty cases, concludes that:

1. Sulphonal is an agreeable medicament, being odorless and tasteless.

2. It acts as a hypnotic in cases of "nervous" sleeplessness, in doses of fifteen to thirty grains. When the insomnia is the direct result of organic disturbances due to existing disease the action is more or less uncertain.

3. Sulphonal does not affect temperature, pulse or respiration, and is to be preferred to morphine and chloral when heart failure is to be feared. It is especially to be commended for children.

4. The subjective manifestations, immediate and subsequent, are insignificant, and not a contraindication for the use of the drug.—*Deutsche medizin. Wochenschr.*, June 21, 1888.

The Symptomatic Value of Optic Neuritis.—MANZ, of Freiburg (Versig. d. Südw.-deutsch. Neurologen u. Psychiater), discussed the symptomatic significance of the optic neuritis which is so frequent in cerebral affections. GRAEFE held the increased intracranial pressure as the cause of the neuritis, while Manz ascribed great significance in the pathogenesis to the communication between the sheath of the optic nerve and the subarachnoid space. LEBER explained the neuritis by the presence of products of disintegration originating in the neighborhood of the cerebral lesions. This view, to which DEUTSCHMANN also subscribed, is, however, hardly probable, and opposed by a number of clinical facts: 1. Variations in the intensity of the papillary changes; 2. The infrequency of optic neuritis in meningitis; 3. The neuritis is very rare in encephalitis suppurativa; should exudation occur, it is serous and not purulent; 4. The neuritis seldom attends apoplectic attacks, though inflammation frequently occurs in the neighborhood of the clot.—*Wiener medizin. Pr.*, July 1, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 28, 1888.

THE RELATION OF ATMOSPHERIC CONDITIONS TO CHOLERA INFANTUM.

THE belief that atmospheric heat and humidity influence powerfully the production of intestinal disease in young children has been for many years prevalent and unquestioned. With the light thrown upon the subject by the study of bacteria and fermentation, this belief has been called in doubt, and recent studies go to show that opinions must be revised, and that the influence of climate is now a moot point.

In a paper read before the New York Academy of Medicine early in the present year, SEIBERT reported the results of ten years' observations on climate and intestinal disease in children, including his personal study of 8000 cases, from which he drew conclusions unexpected alike to himself and to others. He found that a *high* temperature, moist or dry, is not necessary for an epidemic of cholera infantum. Weather, with a *minimum* daily temperature not below 60° F., invariably brings on the disease, and without regard to the maximum daily temperature. When the minimum daily temperature remains below 60° F., cholera infantum ceases to be epidemic. Hence he concludes that this disease cannot be brought about by the direct working of high temperatures on the infantile body, but must have other causes. Rainfall and wind velocity were found to be without influence.

Seibert next ascertained that the milk supply of a city begins to decompose when the temperature exceeds 60° F.; and that vegetable matter contained in the sources of water supply undergoes decomposition, sufficient to be perceptible to the senses, at the same temperature. He considers the food and drink decomposed at certain temperatures, as causes of intestinal disease in young children, and that the direct influence of climate upon the organism is not an etiological factor.

In corroboration of his views are the conclusions reached by MEINERT (*Deutsche med. Wochenschrift*, June 14, 1888), from a statistical study of infant mortality in Dresden and vicinity. He found that it was not high temperature, but the conditions favorable for decomposition which cause cholera infantum. Italy, although warmer, had a lower mortality than Northern Europe, because the atmosphere of dwellings was more constantly changed in the warmer country, and decomposition prevented. A stagnant, warm atmosphere Meinert believes to be an exciting cause of the disease. He regards the fever of cholera infantum as the invasion fever of a zymotic disease, the cause of which becomes pathogenic when the atmospheric condition described is present, and when zymotic changes occur in the child's food.

These results are especially interesting, in view of the more general use of sterilized food for infants, and the antiseptic (or antifermentative) treatment of intestinal disease. While digestion offers so many unsolved problems, we shall do well not to increase the complexity by introducing previously decomposed food; and whether bacteria, or ptomaines, or both, are the active cause of disease, it is essential to hold clear ideas regarding the relative importance of the various factors in this complex problem.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

WE have from time to time given the preliminary programmes of the several societies which are to take part in the meeting at Washington in September next, and from these, taken in connection with the announcement from the local Committee of Arrangements, which we print on another page, it seems quite certain that the meeting will be a very busy one, that some papers of unusual importance will be presented, and that, in a quiet way, due hospitality for the guests and opportunities for social intercourse will be provided.

It seems that the Executive Committee had decided that there should be nothing like a general banquet, and by placing all the work of the Congress

proper in the three evenings, made it practically impossible to have such a banquet during the three days of the meeting. Some members of the different societies wished to have an opportunity to give a dinner to their guests, and have, therefore, united in arranging for such an entertainment on the Monday evening preceding the opening of the Congress. This is, of course, entirely a private entertainment, and the invitations will be confined to the guests of the several Societies forming the Congress.

We have received several requests for information as to how volunteer papers from persons, not members of any of the Societies taking part, can be brought before the Congress, which show that the organization is not understood. The business of the Congress, as a conjoint meeting of all the special Societies, is confined to three evenings, and no papers, except those already provided for, can be presented on those evenings. It is to the individual Societies, which have their meetings during the day, that such papers should be offered.

The final announcement of the arrangement of papers and discussions is to be issued in August. It is understood that the Address of the President, Dr. Billings, will have Medical Museums as its subject.

MEDICAL LEGISLATION IN THE PROVINCE OF QUEBEC.

THE session of the Provincial Legislature of Quebec which has just been prorogued was one of great interest to the medical profession.

In the first place, the Medical Bill, which has exercised the minds of the College of Physicians and Surgeons for the past two or three years, was thrown out, to the great satisfaction of the English-speaking part of the profession. This bill provided that all the subjects of the preliminary examinations in general education should be conducted on the lines of the instruction afforded by the *cours complet* of the French colleges. Had the bill carried, it would have compelled English students either to give up the idea of entering the profession or to obtain their education at one of the French colleges. Now this education is a clerical one and includes many subjects not taught in English schools, such as old-time philosophy, rhetoric, style, etc., and leaves out a thorough instruction in those subjects which, in the opinion of Anglo-Saxons, most fit one to enter successfully on the battle of life.

The bill referred to acknowledges that a B.A. degree from our best English universities was a sufficient guarantee that the individual was qualified to enter on the study of medicine. The student forsooth, must know something of the philosophy of St. Thomas Aquinas in order to combat successfully the heretical doctrines which are now so frequently taught in schools of medicine.

The bill also provided that hereafter no degree from any university whatever should entitle a man to register as a practitioner, but that every one wishing to practise in Quebec Province must pass an examination before the College of Physicians and Surgeons. This portion of the bill was aimed at some of the universities which graduate men too easily, and whose degrees have not the high standing they should have. However, this went with the rest. It is very questionable whether men elected by the general body of the profession, and who are not teachers, are fit to examine in the more scientific branches of the profession, as their appointments are usually made for territorial and political reasons.

A very good health bill was passed which confers enormous powers on the Provincial Board of Health. It is hoped that this Board will make good use of these powers.

The registration bill which was sent up with the health bill was thrown out, so that the registration of births and deaths is still left in the hands of the churches, and the children of those persons who belong to no church fail to appear in the birth list. No certificate of the cause of death is required, so the mortality statistics are now, as they always have been, thoroughly unreliable.

THE Second International Congress for Hydrology and Climatology will meet at Paris early in October of 1889. The precise date has not yet been fixed.

THE University of Bologna has conferred honorary degrees in medicine upon the following representatives of German medicine: Liebermeister, Schiff, Koch, Billroth, Köllicker, Pettenkofer, Ludwig, Virchow and O. Hertwig.

DR. GEORGE M. STERNBERG, U. S. A., and Prof. Hirsch, of Berlin, have recently been elected Honorary Members of the Epidemiological Society of London.

DR. LÖFFLER has been made ordinary Professor of Hygiene, and Dr. Knorr, of Würzburg, the discoverer of antipyrin, Professor Extraordinary, at the University of Greifswald.

Prof. v. Liebermeister, of the medical faculty of the University of Tübingen, has been made a consulting body physician by the King of Wurtemberg.

Professor Max Fürbringer, of Amsterdam, has been elected Professor of Anatomy at the University of Jena.

Prof. Preyer, of Jena, has resigned his professorship to go to Berlin in the fall. The medical faculty of the University has unanimously decided to establish a second chair in anatomy, for which position Prof. Bardeleben is held in view.

At the Commencement Exercises of Union College, in June, 1888, the honorary degree of LL.D. was conferred upon Mr. Lawson Tait, F.R.C.S., Prof. of Gynecology in Queen's College, Birmingham, Eng.

Dr. Charles E. T. Montcalm, the great-grandson of the Marquis de Montcalm de Véran, who fell at Quebec, in 1759, died at Brooklyn, July 17th. He was born at Paris, in 1821, was educated in medicine in that city and at London, and for a time taught chemistry at the Middlesex Hospital. He was secretary to Minister Thiers and held other important positions at Court until 1845, when he went to London, incurring his father's displeasure. He inherited a fortune from his mother, and his mansion at London became a shelter for hundreds of political refugees. His father dying in 1856, he returned to France to attend to his inheritance. This was in the time of Napoleon III., who caused his arrest on political charges upwards of fifteen times, and finally his imprisonment for seven years. He escaped from France in 1864, in the disguise of a priest, and made his way back to London, only to find that his property in France had, during his imprisonment, been drained by governmental fines and charges to the point of confiscation. His home in London had been destroyed by fire while he was a prisoner, as was alleged, by agents of the Empire, for the purpose of securing or destroying certain political documents of a compromising nature. In 1866, finding himself impoverished, he left for America. He lived for ten years in New York City and during the remainder of his life in Brooklyn. He engaged in medical practice and chemical work until about three years ago, when he was compelled by cardiac disease to lay aside his labors.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

The 21st Annual Meeting held at New London, Conn., July 17, 1888.

Morning Session.

Miscellaneous Business.

The Society was called to order by the President, Dr. J. S. Prout, of Brooklyn, who alluded in his opening address to the loss sustained by the Society in the death of Dr. C. R. Agnew, of New York, and suggested that action be taken.

On motion, Dr. Gorham Bacon and Dr. W. H. Carmalt were appointed to prepare an appropriate minute on the subject.

Dr. E. Williams, of Cincinnati, on account of failure of health, presented his resignation. This was accepted; on motion of Dr. Carmalt, the by-laws were suspended and Dr. E. Williams was elected an honorary member of the Society.

Dr. W. H. Carmalt presented the report of the Committee of Conference on the Congress of American Physicians and Surgeons. It was accepted and it was decided that when the Society adjourns, it do so to meet at the Arlington Hotel, Washington, D. C., September 18, 1888, at 11 A.M.

On motion of Dr. Green, it was decided that the meeting should be strictly for scientific matters and should not be regarded as a business meeting; that it should not take the place of the annual meeting.

Dr. C. H. Burnett, of Philadelphia, reported

A case of aural vertigo (Ménière's disease) relieved by excision of the membrana tympani and of the malleus.

The patient was an unmarried woman, thirty-seven years of age, who six years previously had been under treatment for chronic naso-pharyngeal catarrh and chronic catarrh of the left middle ear, accompanied with hardness of hearing, tinnitus aurium and a sense of fulness in the affected organ. Treatment of the catarrhal disease of the ear produced no benefit. After the lapse of six years, the symptoms already named grew worse and there was superadded marked aural vertigo. The membrana tympani, in the line of the malleus-handle, was found adherent to the promontory, and the consequent retraction of the entire chain of bones was held to be the cause of the aural vertigo, of the sense of fulness and of the tinnitus.

The operation of excision of the membrana tympani and of the malleus was performed under ether, May 21st last, with entire and immediate relief to the aural vertigo (which before had often been sufficient to cause the patient to hold to a lamp-post for support), to the sense of pressure and to the tinnitus, which good result has been maintained to the present time. The hearing was practically unaffected by the operation. The incus was detached from the stapes, but could not be removed, as it slipped into the attic, and grappling for it is not advisable, on account of the risk of irritation. Its removal, furthermore, would have no effect on the result of the operation.

Dr. J. O. Tansley, of New York, stated that he had now under observation a girl on whom this operation was performed some eighteen months ago. When she came to him, the whole internal canal was filled with polypi and she presented various brain symptoms. All the polypi were removed, a portion of the drum remaining, and above this was a localized necrosis, into which a probe passed at least one-fourth of an inch. The patient has been under observation every day for two months; the local necrosis is healed and she is doing well. There are still some brain symptoms. It seems that this is a very serious operation, and he would hesitate some time before performing it, on account of the results that might occur. In this case, the result seems directly traceable to the operation.

Dr. Burnett said that, in his case, a discharge appeared two or three weeks after operation. There is still a slight discharge, but the membrane is forming. In another case, a slight discharge appeared soon after the operation, but ceased after the membrane had re-formed. The case reported by the last speaker was not one of the class to which he had alluded. The operation was evidently not properly performed, if there remained a portion of the membrane and there was necrosis. He had not found this a dangerous operation.

Dr. Charles J. Kipp, of Newark, remarked that this operation has been performed a number of times by foreign operators, for the relief of tinnitus and vertigo, but has been given up because it did not relieve these symptoms satisfactorily. There were, however, no bad results.

Dr. Sexton, of New York, had performed this operation between fifty and one hundred times in the past few years, and had obtained decided benefit in a number of cases of tinnitus and other subjective symptoms. He had known of no case in which there was aggravation. In many cases in which there has been no marked tinnitus, the distressing sense of pressure has been overcome. The tinnitus is not always relieved by the operation. His principal endeavor has been to avoid re-formation of the drum membrane. In a number of cases in which this occurs, the good hearing is lost. He prevented this by the application of a solution of salicylic acid in ether to the margin of the closing membrane. This has succeeded even when the membrane has closed down to a minute opening.

Dr. B. Alex. Randall, of Philadelphia, was invited to take part in the discussions of the Society. He said that in Dr. Tansley's case the operation may have been done for the necrosis. The presence of polypi of the size referred to indicates great neglect, and the results are more probably attributable to this neglect than to the operation.

Dr. Sexton then exhibited

A NEW PORTABLE BATTERY FOR THE STORAGE OF ELECTRO-MOTOR FORCE

and

A NEW HEAD-LANTERN FOR THE EMPLOYMENT OF ELECTRIC LIGHT IN SURGERY.

The battery was made, at his suggestion, by the River and Rail Electric Light Company of New York. It consists of three cells, and will light a six-candle electric light. The lantern is a modification of that of Trouve, but much lighter, and having a non-conducting base. Such a light is almost necessary in operations on the ear when ether is used as an anæsthetic. The battery will work continuously for twenty-four hours, and will retain its power for several weeks or months. It may be charged by a dynamo or by twelve gravity cells. When not in use, the storage battery may be kept in connection with the gravity cells.

Dr. A. H. Buck, of New York, then read a paper on

REFLEX INFLUENCE IN THE PRODUCTION OF NASO-PHARYNGEAL CATARRH.

His object was to call attention to those comparatively remote exciting causes of naso-pharyngeal catarrh, which act, so far as it is possible to explain their mechanism, through the intervention of the vasomotor fibres of the sympathetic nerve. We know little of the direct exciting causes of naso-pharyngeal catarrh. The most common indirect cause is chilling of the surface of the body. According to certain authorities, affections of the teeth should rank next in order of frequency. The author has, however, seen very few cases in which dental disturbance played the part of a promoter of naso-pharyngeal catarrh or of aural disturbances. Some of those indirect causes which he has observed were then enumerated. Irritation of the gastro-intestinal canal is, in not a few instances, a strong exciting cause of naso-pharyngeal catarrh and of all the aural disturbances growing out of such a catarrh. A male, forty-five years of age, had, for years, been more or less a sufferer from naso-pharyngeal catarrh with tinnitus aurium and slight impairment of hearing, and more recently had begun to suffer from feeble digestion. He noticed that, after indulgence in certain articles, there would be abdominal discomfort and, at the same time, marked exacerbation of the naso-pharyngeal catarrh. So long as the offending substance was in the stomach, there was only a slight sense of discomfort, but, in the course of three or four hours, a slightly painful peristaltic movement would be set up in the bowels; simultaneously the secretion from the vault of the pharynx would become unpleasantly active and the tinnitus would increase. This condition would last for an hour, and then the naso-pharyngeal catarrh would return to its usual state. These attacks were accompanied with the escape of large quantities of gas by eructation. In many patients, usually men between forty and sixty years of age, in whom we have reason to believe that the gastro-intestinal tract is habitually in a state of greater or less irritation, we find the faucial mucous membrane red and swollen. In these cases, the disease which claims chief attention is the gastro-intestinal affection.

Reflex influences, involving the vault of the pharynx and the ear, may emanate from more distant sources. A lady, forty years of age, complained of distressing tinnitus, involving both ears. There had been mild naso-pharyngeal catarrh, from time to time, for many years. At times, she was almost entirely free from tinnitus. Dr. Buck always succeeded in giving prompt relief by applying to the vault of the pharynx a moderately strong solution of silver nitrate with a mop of absorbent cotton. After a time, these failed to give relief. It was then he learned that, for many years, she had suffered with pain in the pelvic regions and back, and that, at this particular time, she was suffering in a more marked degree. A specialist was then consulted and it was found that there was retroversion of the uterus and subacute parametritis. These

conditions were removed and the tinnitus disappeared without treatment to the vault of the pharynx.

He had spoken of these as indirect causes—that is, as factors competent to aggravate a preëxisting, but perhaps latent, catarrhal disease; but he saw no reason why these reflex influences may not, in certain cases, play the part of direct exciting causes. He considered it impossible to demonstrate the correctness of this belief, and therefore preferred to adopt the view which assigns to them a less independent *rôle*.

Dr. Tansley had met with many cases of naso-pharyngeal catarrh in girls, fifteen to twenty years of age, who are decidedly anæmic and chlorotic, and who suffer with constipation, and had found that this was the cause of the catarrhal symptoms.

Dr. S. D. Risley, of Philadelphia, said that it was generally admitted that nasal and pharyngeal diseases are especially liable to occur in persons of a gouty diathesis. Naso-pharyngeal disease is one of the most uniform manifestations of lithæmia. Some of the symptoms detailed in regard to the first case of Dr. Buck suggested that the digestive disturbance was probably associated with a lithæmic condition.

Dr. Burnett had seen a number of cases of tinnitus, without deafness, due entirely to dyspepsia. The use of nitrate of silver had been referred to. While this may be of service in other locations, it is the worst application that can be made to the nose or the naso-pharynx. Its use will be followed, sooner or later, by sclerosis and atrophy. It will apparently cure a hypertrophic catarrh, but the case comes to the rhinologist later with a marked atrophic process in the mucous membrane. He had entirely abandoned the use of nitrate of silver for affections of the nares.

Dr. Sexton referred to the fact that, in many cases, irritation in the mouth has been the cause of naso-pharyngeal catarrh and aural symptoms. A lady was brought to him, with intense pain in the ear and head. There was nothing in the condition of the ear to account for these symptoms. Examination of the mouth showed that she was wearing a plate to bring the teeth closer together. The gum was intensely inflamed, although the patient complained of no discomfort. The removal of the plate caused a disappearance of the pain in the ear and head.

Dr. Tansley had met with many cases in which irritation of the teeth caused aural symptoms. He agreed with Dr. Burnett that nitrate of silver should not be used in the nasal cavity. He had not made such an application for a number of years. There is in catarrh an increased thickening of the basement membrane; this tends to contraction and the tendency to contraction is increased by the use of nitrate of silver. He employs such agents as induce an exosmosis.

Dr. J. F. Noyes, of Detroit, remarked that the paper brings up the fact that it is important that, in our special practice, we should consider general practice. He had always recognized those so-called reflex causes, and had treated cases by searching out these causes. A remarkable case of a lady, who after confinement developed naso-pharyngeal catarrh, came under his notice. There was profuse secretion. The trouble continued for a year, in spite of treatment. Finally, she passed into the hands of a gynecologist. The cause was discovered and treatment of the uterine disease cured the naso-pharyngeal disease.

Dr. Samuel Theobald, of Baltimore, held that, when atrophy follows hypertrophic catarrh, it is the result not of the application of nitrate of silver but of the continuance of the catarrh. He questioned whether solution of nitrate of silver, ten to fifteen grains to the ounce, will produce sloughing, and regarded this agent as a valuable application in disease of the nasal membrane.

Dr. Charles J. Kipp, of Newark, agreed with Dr. Theobald as to the value of nitrate of silver. He rarely uses it in a stronger solution than twenty grains to the ounce, and neutralizes it afterward by salt water.

Dr. Henry D. Noyes, of New York, had frequently noticed the connection between the lithæmic condition and certain affections not only of the naso-pharynx but also of the external auditory canal. There are certain eczematous conditions of the ear associated with the gouty diathesis.

Dr. F. P. Capron, of Providence, referred to a number of cases of so-called hay-fever, in which the premonitory symptoms were those of indigestion. For two or three weeks before the time of the onset of the regular attack, the patient would complain of digestive disturbance.

Dr. A. H. Buck, of New York, then presented

A CONTRIBUTION TO THE ANATOMY OF THE ELEPHANT'S EAR.

The ear was exhibited and the interesting points indicated. The external auditory canal is imbedded in air-containing cells and is six and a half inches long. The canal at the time of examination was filled with desquamated material. In the middle ear, the handle of the hammer seems to lie in a horizontal plane. It is not vertical, as in the human being. The anterior part of the drum cavity is completely cut off from the posterior part. The Eustachian tube comes up through a system of air cells and opens through one of them close to the drum membrane. Under the floor of the tympanic cavity, there are three septa, making stall-like spaces. Two of these are quite long, six or seven inches. The labyrinth and other parts were not examined.

Dr. Huntington Richards, of New York, through Dr. Buck, reported

A CASE OF POLYPOID ANGIOMA OF THE EAR.

The patient, a girl six years of age, came under observation May 4, 1888, with profuse and badly smelling otorrhœa, unaccompanied by pain and dating only from the preceding February. Hearing seemed good. No bleeding from the ear had ever been observed. The general health was excellent.

Examination of the affected ear revealed a polypoid mass almost occluding the canal. The color was deep purplish-red. A considerable portion of the tumor was at once removed with the snare and the remainder of the growth was extracted on the following day, leaving a small pedicle attached, seemingly to the outer surface of the drum membrane close to the prominence formed by the short process of the hammer. This stump was cauterized with chromic acid. Hemorrhage from the cut surface of the growth was unusually profuse at both operations. The child's hearing is now excellent, although both membranes are depressed and of a dark grayish-red color. The removed growth was pronounced

to be an angioma. Three micro-photographs showing the appearance of the growth were exhibited.

He also reported the following

CASE OF FALSE-DRUM MEMBRANE.

The patient, a man, twenty-one years of age, was totally deaf in the affected ear. There was a vague history of an attack of otitis media in early childhood. The other ear presented the common appearance of otitis media purulenta chronica. Examination of the ear that was not discharging showed a membrane occluding the canal. It differred from the normal-drum membrane in color, shape, relation of its plane to the long axis of the canal and apparent thickness. It varied little in color from the skin lining the canal. The surface was perfectly smooth.

A triangular opening was made through this membrane. This caused no pain. Through this opening, it was seen that there was no drum membrane, but the inner wall of the tympanic cavity came into view. The hearing was only slightly improved. When seen a few days later, no discharge had appeared. Since that time he has not returned to the Infirmary.

Dr. Sexton had seen several such cases as that described in the last paper. In a case seen last year, he removed the membrane and then took out the malleus and incus. This case made a good recovery. The improvement in hearing was decided. He suggested this operation in such cases, as a possible means of improving the hearing, for it opens up the tympanic cavity, which is a good condenser of sound; and in the second place, to prevent the accidental occurrence of inflammation in these parts, when it might be difficult to obtain relief.

Dr. T. Y. Sutphen, of Newark, had seen one or two cases of this trouble, which seemed to him to be due to cicatricial closure of the external canal. It seemed that the condition would be best spoken of as cicatricial closure of the canal.

Dr. Kipp said that these cases result from granulations, and he had watched the formation of these membranes. In treating the condition, he incised the membrane and put in laminaria bougies.

Dr. A. Matheuson, of Brooklyn, remarked that a lady was under his care for some time with an eczematous condition of the external meatus. She then passed from observation. Some time later, she presented herself with a disk-like closure of the external canal. This was not complete, as there was a small opening in the centre. He dilated this opening with laminaria bougies, and the ear was left in perfect condition.

Dr. Theobald had reported a case in which there was occlusion of both external canals. There was a history of suppuration, and no doubt there was ulceration and gradual closure.

Dr. Burnett had seen several of these cases of dermoid diaphragms in the canal. Three of these were in private practice. One was in an old man, and it remained imperforate during the whole time he was under observation. The other cases were perforate when they came. There was slight discharge which was checked, and the perforation healed. In one case the discharge returned after a short time and the perforation reappeared. Under treatment it healed and had remained closed since, a period of four or five years. In the other case it remained closed for a year, when the opening returned with slight discharges. The discharge ceased under treatment, the opening closed and has remained closed.

Dr. Randall said that in the case of a boy, twelve years old, in which there was closure of the meatus as a result of injury with forceps during labor, he excised the diaphragm. The cavity was thoroughly washed out. The case was then treated in the ordinary way. The hearing obtained was certainly one-fourth of the normal.

Evening Session.

Dr. J. B. Emerson, of New York, read a paper on

THE FLEXIBLE CATHETER AS A DRAINAGE TUBE, WITH CASES.

He cited several cases exhibiting the use of the flexible catheter as a drainage tube.

With deeply seated inflammation of the auditory canal or mastoid cells, maintenance of drainage through a fistula is a necessity; and to prevent closure of the fistula, either by granular growth or natural healing, is important. He recommends the use of the flexible catheter as generally the best means to employ and states his reasons to be the comparative comfort and safety, together with the convenience of control by both surgeon and patient. The efficiency observed in the use of the flexible catheter was also referred to.

Dr. O. D. Pomeroy, of New York, said that some years ago he had recommended the use of soft rubber tubing in suppurative otitis in little children, with closure of the canal with no changes except swelling. The canals are so small that the tube cannot be pushed in in the ordinary manner. A piece of small tubing was hooked to the extremity of a notched probe which passed through it. The tube was then drawn tight, thus reducing its size. In this way it could be readily introduced; when the tube was released, it tended to resume its proper size and the probe was withdrawn. Almost all these cases did well.

Dr. Kipp then reported

THREE CASES OF TRANSIENT BILATERAL HORIZONTAL NYSTAGMUS, IN CONNECTION WITH PURULENT INFLAMMATION OF THE MIDDLE EAR.

Case I.—A young man, twenty-one years of age, had had otorrhœa seven or eight years previously. Three months before he came under observation, he had an acute exacerbation and suffered at intervals with pain in the ear and head. The otorrhœa much diminished. Two or three weeks later, he came, stating that he saw objects double, was dizzy and could not walk. There was marked nystagmus in a horizontal direction. The vertigo and nystagmus continued four days. With the cessation of the nystagmus, the vertigo disappeared.

Case II.—A young man, treated six years previously for acute otitis media purulenta ending in recovery, appeared in March, with an acute attack. Paracentesis was performed. The pain, however, continued for a long time. Finally, swelling developed behind the mastoid, and this was accompanied with several epileptiform attacks. One day, pressing on the swelling, pus poured from the canal. With this there was a sudden jerk of the head and nystagmus. The latter continued for about ten minutes. This was produced every time pressure was made on the mastoid. The mastoid was subsequently opened. Since then there has been improvement.

Case III.—A young man, after exposure, was seized with intense pain in the ear, followed by otorrhœa. When he came under observation there was great pain. This was not relieved by treatment, but continued two or three weeks. Then a swelling appeared below the ear. This was incised and a large quantity of pus evacuated, with relief to the pain. Some days later, while washing out the cavity, the fluid came through the ear when considerable force was used. At the same time, there was a jerk of the head and nystagmus continuing several minutes. This could always be produced by making a forcible injection.

Dr. Pomeroy said that reference had been made to epileptiform symptoms in one of the cases. He had recently seen a case of epilepsy in which the exciting cause was suppuration of the middle ear. With recovery from the ear disease, the convulsions ceased and have not returned.

Dr. Tansley exhibited

AN IMPROVED AURAL SNARE,

devised to overcome an objection in the ordinary Wilde snare, that is, the little jerk and rebound of the instrument when the growth is cut through. The instrument exhibited consists of a small tube, through which the wire passes to be connected with a small bobbin, by the turning of which it is gradually shortened.

Executive Session.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. J. S. Prout, of Brooklyn.

Vice-President.—Dr. Gorham Bacon, of New York.

Secretary and Treasurer.—Dr. J. J. B. Vermyne, of New Bedford, Mass.

Committee on Membership.—Dr. A. Mattheuson, Dr. D. B. St. John Roosa and Dr. John Green.

Members of Executive Committee of Arrangements of Congress of American Physicians and Surgeons.—Dr. W. H. Carmalt, of New Haven; Alternate Dr. G. Bacon, of New York. The Society then adjourned to meet at the Arlington Hotel, Washington, D. C., Tuesday, September 18, 1888.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-fourth Annual Meeting, held at New London, Conn., July 18 and 19, 1888.

Wednesday, July 18th.—Morning Session.

The Society was called to order by the President, Dr. W. F. Norris, of Philadelphia.

MISCELLANEOUS BUSINESS.

Dr. H. D. Noyes, of New York, read a memorial of the late Dr. C. R. Agnew.

Drs. W. H. Carmalt and C. S. Bull were appointed a committee to prepare an appropriate minute in regard to the death of Dr. E. G. Loring; and Dr. Charles J. Kipp was appointed to prepare a similar minute in regard to the death of Dr. Joseph Oub.

Dr. C. S. Bull, of New York, presented

A CONTRIBUTION TO THE TREATMENT OF MEMBRANOUS OPACITIES IN THE VITREOUS HUMOR.

These opacities, in the form of membranes or shreds, are rarely freely movable and usually resist internal treatment. Operation by incision with a needle was first performed by von Gräfe. In the experience of the writer, the operation had been found useful. Some opacities resulting from hemorrhage or from inflammation of the choroid respond to internal remedies, but, as a rule, these remedies fail. By incision of the membrane a direct improvement of vision may be obtained and the process of absorption may be stimulated. Posterior opacities are more easily reached, with less danger to the lens and with more favorable results than in the case of anterior opacities. The author has performed this operation in seventeen cases of chronic membranous deposits in the vitreous. In some cases, the ordinary incision needle was used, in others, a broader needle, and in a few, a slender cataract knife. Cocaine was employed in all cases. The point selected by preference for the introduction of the needle was just in front of the equator of the eye and below the insertion of the external rectus muscle. There seems in this operation to be no danger of loss of vitreous through the small opening, nor is there danger of hemorrhage. The puncture should be posterior to the ciliary process, and pressure with the forceps should be avoided. As a rule, little or no reaction follows the operation. A protective bandage is required only a few days. Antiseptics were employed in all cases.

The details of the seventeen operations on fifteen patients were given. Fourteen showed decided improvement in vision. Three were failures. There was no loss of vision from the operation in any case. The operation is appropriate in certain cases, but it is wise to wait until all inflammatory symptoms have subsided before attempting any operative procedure. The eye should be absolutely free from all irritation before surgical interference is attempted.

Dr. W. F. Mittendorf, of New York, thought that vascularity of the vitreous membrane should always speak against operations of this kind. Vascularity, even if all inflammatory signs have subsided, points to a fatal prognosis.

Dr. F. Buller, of Montreal, reported

A CASE OF PULSATING EXOPHTHALMOS CURED BY LIGATURE OF THE COMMON CAROTID ARTERY.

He had seen four cases of this affection. In the first the condition followed a blow upon the head. Some months after the appearance of the pulsatory exophthalmos, ligation of the carotid was performed, but the patient died in the course of a few weeks from repeated attacks of epistaxis. The second case has already been reported.

In the third case the affection followed a blow on the brow with a piece of iron. The patient was seized with severe epistaxis and died in a few minutes. There was found a depressed fracture of the frontal bone, with a fissure extending across the orbital roof and the body of the sphenoid bone directly beneath the cavernous sinus. As a result of caries of the bone there was a direct communication between the nasal cavity and the internal carotid artery.

The fourth case, the subject of the paper, came under

observation May 24, 1888. A man, aged twenty-eight, fell a distance of twenty feet, striking the right side of his head, rendering him unconscious for twenty-four hours. After the swelling had subsided, the patient noticed diplopia, one image being higher and less distant than the other. There was also a loud beating sound in the right ear. Two weeks before coming under observation, prominence of the eye was noticed. There was still diplopia, the higher image moving up and down with each heart-beat. Four days before coming under notice, the pain became intense. On examination there was found at the inner extremity of the right brow a swelling which imparted a distinct thrill to the finger. There was also a harsh bruit. Pressure over the common carotid artery diminished the intensity of the thrill and lessened the pulsation.

It was decided to ligate the common carotid in the upper part of its course, and this was done May 25th, two ligatures being applied and the vessel being divided between them. The immediate effect was softening of the swelling, partial reposition of the eyeball, great diminution in the pulsation and disappearance of the bruit. The patient made a good recovery, and left the hospital with very little prominence of the ball. $V = \frac{20}{XX}$. H. Movements normal.

Dr. Charles J. Kipp, of Newark, reported a case of

PULSATING EXOPHTHALMOS.

A lady, seventy-six years of age, presented herself, with the history that, shortly after striking the head in a fall, she noticed a noise in both ears, followed by protrusion of both eyeballs, the right four-tenths of an inch, the left two-tenths. There was no marked pulsation, but there was a thrill, and a bruit could be heard over the anterior half of the head. This could be arrested by compression of the right carotid artery and partially so by compression of the left carotid. In view of the age of the patient, no radical measures were recommended, but it was suggested that pressure be made on the right carotid as often as convenient. Iodide of potassium was also given. Three months later the patient stated that the noise had suddenly disappeared. This was followed by the diappearance of the exophthalmos, first in the left eye and subsequently in the right. The external appearance of the eyes is now normal. There is, however, a marked pulsation of the right subclavian artery, but no aneurism can be discovered.

Dr. D. S. Risley, of Philadelphia, called attention to the fact that Dr. Harlan had reported a case of this kind cured by compression, and that he had himself reported a case in which compression of the vessel for a short time was followed by the disappearance of the symptoms and the subsidence of the exophthalmos.

Dr. Swan M. Burnett, of Washington, presented an

ANALYSIS OF 576 CASES OF REFRACTION OF HEALTHY HUMAN CORNEÆ, EXAMINED WITH THE OPHTHALMOMETER OF JAVAL AND SCHIOTZ.

These 576 corneæ belonged to 301 persons examined within a little over a year by Dr. Burnett. Pathological states of the cornea were excluded for consideration at another time. The corneal refraction was found to be the same in both eyes to within 0.25 D. in 110 persons. The horizontal meridian (to within 5°) was the least refractive (astigmatism according to the rule) in 420 eyes. The vertical meridian was the least refractive (astigmatism against the rule) in 20 eyes. In 88 eyes the meridians were oblique. In 58 eyes the difference in the refraction of the two meridians was less than 0.25 D. In 101 eyes there was emmetropia. The largest number had a corneal refraction of from 44 D. to 45 D.; the next largest from 43 D. to 44 D. The strongest corneal refraction was 47 D., the weakest 39 D. In 55 eyes there was simple myopia. The strongest refraction in the weakest meridian was 47.25 D.; the weakest 39 D. The corneal refraction did not in any considerable number of cases bear any close relation to the degree of the myopia. Simple hypermetropia was present in 59 eyes. Weakest refraction in the weakest meridian was 40.5 D.; the strongest 46 D. As in myopia, the corneal refraction was no indication as to the degree of general hypermetropia. Myopic astigmatism was found in 140 eyes. In 4 eyes the general astigmatism was greater, and in 11 it was less than the corneal. In 14 eyes the difference in the axes of the corneal membrane and that of the prescribed glasses was greater than 5°. Hypermetropic astigmatism was present in 96 eyes. In 4 eyes the corneal astigmatism was greater, and in 2 eyes it was less than the general. The axes corresponded in all but 9 eyes. Compound myopic astigmatism existed in 63 eyes. In all but 7 eyes the corneal and general astigmatism corresponded, and in 44 eyes the axes corresponded. Compound hypermetropic astigmatism was found in 55 eyes. In 31, corneal and general astigmatic meridians corresponded. The corneal and general astigmatism was the same in all but 4 eyes. Mixed astigmatism was present in 8 eyes. In 4 the corneal and general astigmatism was the same. In 2 the corneal was less and in 1 greater than the general. Corneal and general astigmatic meridians were the same in 5 eyes. In 42 eyes the general astigmatism was against the rule, while in only 18 of these eyes was the corneal astigmatism against the rule. From examinations under a mydriatic, the author felt himself warranted in thinking that many cases of lenticular astigmatism are due to an oblique position of the lens.

Corneal astigmatism is, with very few exceptions, according to the rule (vertical meridian the stronger). From study of these statistics, the author feels warranted in concluding that while the corneal refraction gives no indication of the general refraction of the eye, its astigmatism, in the vast majority of cases, expresses the general astigmatism, both as to degree and direction of its axis, and he considers, therefore, the instrument of Javal and Schiotz one of if not the most important instrumental means for the diagnosis of the anomaly. He does not think astigmatism more productive of progressive myopia than any other form of ametropia.

Dr. Noyes had used the ophthalmometer of Javal and Schiotz with great satisfaction. In the immense majority of cases the evidences of the ophthalmometer, without the use of atropine, have corresponded with the evidences of the trial case. The amount of astigmatism and, in a general way, the axis of the astigmatism is obtained. The use of this instrument has led him to believe that mixed astigmatism is more common than we usually imagine. He also noted the influence of the eyelids in altering the curvature of the cornea, and had satisfied himself that the tension of the eye muscles modifies the

curvature of the cornea. He had also noticed in some cases a pulsation of the corneal reflex, due to the fact that the cornea was so thin that the circulation of the eye impressed itself upon it. This was seen particularly in conical corneæ. The use of this instrument does away, to a large extent, with the necessity for the employment of atropine.

Dr. Samuel Theobald, of Baltimore, inferred that the author thought that, when a mydriatic was employed, the lenticular astigmatism was done away with. His experience led him to believe that the asymmetrical condition of the lens does not at once disappear on paralysis of the ciliary muscle. The discrepancy between the total and general astigmatism may often be accounted for by this persistent asymmetrical condition of the lens. This condition gradually disappears after suitable glasses are worn.

Dr. B. Alex. Randall, of Philadelphia, could not agree with the author, that simple astigmatism is so common and predominates over other forms. Taking the records of the Hospital of the University of Pennsylvania for the last ten years, he found 4000 refraction cases determined, almost without exception, under a mydriatic. Compound hypermetropic astigmatism constituted about 40 per cent.; compound myopic astigmatism constituted 30 per cent.; simple myopia and hypermetropia about 8 per cent. and 12 per cent. respectively; mixed astigmatism, only about 1 or 2 per cent.; compound astigmatism constituted at least 70 per cent. of the total number of cases.

Dr. Edward Jackson, of Philadelphia, exhibited

A NEW FORM OF CATARACT KNIFE,

designed to combine the advantages of the Gräfe and Beer knives. The point, resembling that of the Gräfe knife, allowed the puncture and counter-puncture to be made in the same way as with the Gräfe knife; whilst the rest of the blade, having the shape of Beer's knife, enabled one to complete the incision as with that instrument. With it the puncture and counter-puncture are completely under control, the flap is completed at a single thrust, the aqueous is not lost until the incision is nearly finished, and the counter-pressure, by the back of the knife, assists in steadying the eye.

Dr. Edward Jackson read a paper on

ŒDEMA OF THE CHOROID AND RETINA.

He reported the case of a young man, struck in the eye with a marble or small stone, causing a bruise of the eyeball. The ophthalmoscope showed localized swellings of the choroid and retina at the posterior pole of the eye; the choroidal spots having the usual grouping of ruptures of the choroid in that region. These spots disappeared in about a week. There was also at first some 0.75 D. myopic astigmatism, which gradually diminished, and in three weeks entirely disappeared, leaving the sight perfect.

Dr. W. F. Mittendorf, of New York, then presented a paper on

SYMPTOMATIC MYOPIA.

But little attention has been called to myopia as a symptom of various affections of the eye. Three-fourths of the cases of myopia may be spoken of as: axillary, refractive and symptomatic. The latter form may be caused by traumatism, but more commonly by diseased conditions. It may be produced by displacement of the lens forward. More frequently it is due to swelling of the lens accompanying beginning cataract. This is sometimes relieved by the use of concave glasses; very strong glasses being occasionally required. Plastic exudations may also cause myopia, but these usually so interfere with vision that it is impossible to demonstrate the existence of myopia. Glaucoma, serous choroiditis and iritis are frequently accompanied with myopia as a symptom. A number of illustrative cases were cited. In these cases the myopia was not permanent, but as the disease disappeared the myopia passed away, leaving the refractive condition of the eye the same as before the attack.

Dr. J. O. Tansley, some years ago, reported a case of localized exudative choroiditis just beneath the macula, with myopia. The myopia gradually increased as the attack reached its height, and as the inflammation subsided the myopia passed away.

Dr. Carl Koller, of New York, thought that, in these cases of myopia in iritis, the condition might be due to the irritation of the ciliary muscle. There is hyperæmia of the ciliary body, and as the irides are contracted it is to be supposed that the ciliary muscle is also contracted. Although atropine may be used, there is not full dilatation of the irides. It is, therefore, reasonable to suppose that the myopia is a result of spastic contraction due to inflammation.

Dr. Risley said that in a few instances it had seemed to him that in these cases of iritis and choroiditis the myopia was due to the dread of light and the cramp of the lids.

Dr. John Green, of St. Louis, had, in two attacks of iritis, of which he was himself the subject, carefully studied this myopia. In his case the eyes were completely under the influence of atropia. The pupils were dilated and the ciliary muscle paralyzed.

(To be concluded.)

CORRESPONDENCE.

THE DANGERS OF COCAINE.

To the Editor of The Medical News,

Sir: Dr. Sims's case of death from cocaine, in The Medical News of to-day, carries its own comment.

In my recent reprint—at command of any desiring it—more than 120 cases, some of them fatal, of toxic effect from this drug are cited. In a second edition, nearly ready, several others—one lethal—will be noted, proving, beyond dipute, the statement in The Medical News of April 9, 1887, that "it certainly seems of the greatest importance that the profession in general be reminded that cocaine is not to be used recklessly and without proper care;" and that of *The Medical Press and Circular* of May 23, 1888, that "We do not know the lethal dose of cocaine, and we are not certain of its physiological action, nor do we know the influence of age and disease on its action, but we do know that a powerful therapeutic agent should be used with extreme care when there is so much uncertainty as to its effects;" and that of *The British Medical Journal* of January 21, 1888, that "If it were needful to produce more proof of the unsoundness of Dr. Hammond's statement, Dr. Mattison has effectually done this." Yours, very cordially,

J. B. Mattison.

314 State St., Brooklyn, July 21, 1888.

NEWS ITEMS.

The Congress of American Physicians and Surgeons.—The Committee of Arrangements announces that the arrangements are sufficiently advanced to assure the success of the First Triennial Session of the Congress of American Physicians and Surgeons, which will be held in the city of Washington, during the 18th, 19th, and 20th of September next.

A number of distinguished foreign physicians and surgeons have signified their acceptance of the invitation to attend, among whom may be named Sir Spencer Wells, Sir Andrew Clark, Sir William MacCormac, Drs. W. O. Priestley, William Ord and Grainger Stewart, Mr. Lawson Tait, Mr. Victor Horsley, Mr. Thomas Bryant, Mr. Thomas Annandale, Professors Ferrier, Esmarch and Gerhardt, Drs. Rafael Lavista, of Mexico, and J. L. Reverdin, of Geneva.

The preliminary programmes of the participating societies have already been published. The classified and final programmes will be printed and distributed at an early day.

Places of meeting for the Congress and each of the Societies have been secured, conveniently located, so that members may interchange attendance without annoyance. All the sessions will be open to the profession.

The meetings of the Congress will be held in the evenings, beginning at 8 o'clock P. M.; on the evenings of the 18th and 19th the meetings will be held in the main hall of the Grand Army Building, 1412 and 1414 Pennsylvania Avenue, and on the last (Thursday) evening in the Hall of the National Museum. During this evening the Army Medical Museum and Library building, alongside of the Museum building, will be lighted and opened for the inspection of the members and invited guests.

The meetings of the special societies will be held during the day, according to the programme of each, at the following places:

American Surgical Association, Main Hall, Grand Army Building, 1412 and 1414 Pennsylvania Ave.

Association of American Physicians, Hall No. 1, Grand Army Building, 1412 and 1414 Pennsylvania Ave.

American Climatological Association, Hall No. 2, Grand Army Building, 1412 and 1414 Pennsylvania Ave.

American Laryngological Association, Hall No. 3, Grand Army Building, 1412 and 1414 Pennsylvania Ave.

American Dermatological Association, Parlor in Willard's Hotel.

Association of Genito-Urinary Surgeons, Parlor in Willard's Hotel.

American Neurological Association, Parlor in Willard's Hotel.

American Orthopedic Association, Welcker's Hotel, Fifteenth Street N. W.

American Otological Society, Arlington Hotel, Vermont Ave.

American Physiological Society, Army Medical Museum.

American Ophthalmological Society, Arlington Hotel, Vermont Ave. and H Street.

American Gynecological Society, Columbian University, Fifteenth and H Streets N. W.

American Association of Obstetricians and Gynecologists, National Medical College Building, H Street N. W.

On Monday evening, September 17th, a dinner will be given by members of the Congress to the guests of the participating societies. It will be limited exclusively to members of the Congress and invited guests. Members desiring to participate are requested to notify the Chairman of the Committee of Arrangements.

An informal collation will be served at Willard's Hotel on Tuesday evening, after the adjournment of the session of the Congress. A similar entertainment will be served in the National Museum building on Thursday night, after the final adjournment of the Congress.

The Secretaries of the special Societies are requested to forward to the Chairman the names and addresses of their foreign guests.

Guests are requested to notify the Chairman immediately after their arrival in Washington, of their address and whether they have ladies with them, for the entertainment of whom special arrangements will be made.

Members of the Congress and the guests are expected to register. A Registration Office will be opened in a parlor in Willard's Hotel, from which the mail of the members and guests will be distributed, and at which the city residence of each member or guest can be ascertained.

All communications to the Committee of Arrangements should be addressed to Samuel C. Busey, M.D., Chairman, 1545 I Street, N. W., Washington City.

The British Laryngological and Rhinological Association, recently constituted, held its first general meeting on June 29th, and Sir Morell Mackenzie was elected President, and Mr. Lennox Browne, Dr. G. Hunt Mackenzie and Dr. P. C. Smyly, Vice-presidents.

Investigations, by Dr. Makara, into the Etiology of Carcinoma, are in progress at the surgical clinic of Prof Kovác, at Budapest. The results thus far are negative; specific microörganisms were found neither in carcinoma nor in sarcoma.—*Münchener medizin. Wochenschr.*, July 3, 1888, from *Pest med. chir. Presse*, No. 27.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 24 TO JULY 30, 1888.

VICKERY, RICHARD S., *Major and Surgeon* (U. S. Army).—Leave of absence extended two months.—*S. O. 166, A. G. O.*, July 19, 1888.

CORSON, JOSEPH K., *Assistant Surgeon* (U. S. Army).—Leave of absence for one month, with permission to apply for an extension of one month.—*S. O. 78, Headquarters Department of the Columbia, Vancouver's Barracks, Washington Territory*, July 13, 1888.

DAVIS, WILLIAM B., *Captain and Assistant Surgeon* (U. S. Army).—Will proceed to Fort Niagara, New York, for the purpose of completing his target practice for this year with Company "C," Twenty-third Infantry. Upon completion of this duty, Captain Davis will return to Fort Porter, New York.—*S. O. 145, Headquarters Division of the Atlantic, Governor's Island, New York City*, July 17, 1888.

ROBERTSON, REUBEN L., *Assistant Surgeon* (U. S. Army).—Is relieved from duty at Fort Keogh, Montana Territory, and will report to the commanding officer at Fort Buford, Dakota, for duty at that post, and by letter to the commanding general, Department of Dakota.—*S. O. 167, A. G. O.*, July 20, 1888.

WOOD, LEONARD, *First Lieutenant and Assistant Surgeon* (U. S. Army).—Is relieved from duty at Fort Huachuca, Arizona Territory, to take effect at the expiration of his present leave of absence, and will report to the commanding officer, Fort McDowell, Arizona Territory.—Par. 14, *S. O. 162, A. G. O.*, July 14, 1888.

VOL. LIII. SATURDAY, AUGUST 4, 1888. NO. 5.

ORIGINAL LECTURES.

THE CEREBRAL PALSIES OF CHILDREN.

Clinical Lectures delivered at the Infirmary for Nervous Diseases.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, PHYSICIAN TO THE PHILADELPHIA AND UNIVERSITY HOSPITALS AND TO THE INFIRMARY FOR NERVOUS DISEASES.

LECTURE IV.

SPASTIC PARAPLEGIA.

SYNONYMS.—Paraplegia cerebralis spastica (Heine). Tetanoid pseudo-paraplegia (Seguin). Spastic spinal paralysis (Erb). Tabes dorsalis spasmodique (Charcot).

Spastic paralysis of the legs is a common affection, and yet it is only within the past few years that the subject has attracted much attention from writers on diseases of the nervous system. The orthopœdic surgeons have for years past described and figured cases of this sort in children, which in reality form no inconsiderable quota of the patients at their clinics. Heine, as early as in 1840, gave an admirable account of it and expresses the modern conception of the disease in the name which he applies —*paraplegia spastica cerebralis*. Delpech, Stromeyer, Adams and more particularly Little, describe it in their works already referred to. Erb[1] and Seeligmüller,[2] in Germany, and Gee,[3] in London, brought the subject to the notice of physicians, and the former author described the cases with those of spastic paraplegia of adults. Ross,[4] Hadden,[5] Gowers,[6] d'Heilly[7] and Gilbert[8] have more recently dealt with the question, and the disease is now usually assigned a place among the cerebral palsies of children.

SYMPTOMS.—The general features of the disease may be thus defined: Spastic paralysis of the lower extremities dating from birth, or coming on within the first years of life; absence of wasting; a condition of talipes equinus or equino-varus; adductor spasm, producing the "clasp-knife rigidity;" the gait stiff, the patient walking on the toes, or there may be cross-legged progression. The intellect is usually impaired, though not so profoundly affected as in bilateral hemiplegia.

Case I.—Samuel B., æt. fourteen years. Parents alive and healthy. Three other children, one died of cholera infantum. Born at term, instruments not used, labor easy. "Nervous" at birth. At about nine months began to cry out at nights and would draw up both feet as if in great pain. Never stood alone or walked. Now with assistance can walk a little. Cannot read; mother says he can sing. Cannot speak at all distinctly; voice very thick. Sits bent over double, head hanging on chest; cannot sit upright for more than a moment. Moves head and body constantly. Knee-jerk marked. Ankles, knees and hips stiff. Feet turned out at ankle, knock-knee. In walking, puts toe to ground first. Pupils equal. Expression idiotic. Neck large, circumference fourteen inches. Trapezius and sterno-cleido muscles much enlarged. Tongue long. Teeth: two upper incisors a little chisel-shaped; lower teeth well formed. Head diameters: biparietal, five and one-quarter inches; occipito-frontal, six and one-half inches. Hands strong, well developed. Heels much drawn up. Can flex legs and feet. Ankle clonus present. Muscles of legs not so well developed as those of arms. Spine flexible, no scoliosis.

Case II.—Veria M., æt. thirteen years. Mother living, father killed. Five children living, four dead. Two born dead, one by craniotomy. This child born at eight months; no forceps; labor long and hard. Nursed at breast; spasms at four months and again at six. Never could walk alone until fourth or fifth year. *Present state:* Left leg twenty-four and one-half inches long. No ankle clonus. Right leg twenty-five and one-half inches long. Knee-jerk + +. Gait spastic; cannot walk without crutches. Patella drawn above condyles of femur by quadriceps extensor. Dentition tardy. Arms normal. Head: biparietal diameter, five and one-quarter inches; occipito-frontal, seven inches; circumference twenty and three-eighths inches. Bright, but queer.

Case III.—Addison D., æt. nine years. M. 5, 342. Deformity first noticed at fourteen months. Has never walked, sits doubled up with spine curved. Thighs look large, owing chiefly to large development of fat. Thigh can with difficulty be flexed on abdomen, pelvis rises on flexing thigh; knee very stiff, but can be gradually overcome. Legs much wasted; knee-jerk −. Toes are flexed and he cannot move them. Foot everted. Creeps about and walks with assistance on the outer side of his feet. Head well shaped: biparietal diameter six inches; occipito-frontal, seven inches; circumference twenty-one inches. Intelligence good, can read. Distinct nystagmus, convergent strabismus. Teeth well formed. Arms normal. Electrical examination: responds actively to faradization.

Case IV.—John P., æt. four years. I. P., 4, 4. Parents healthy. Had convulsions at ten months; paralysis of legs, which are rigid. Now creeps on knees, equino-varus of both legs; reflexes +.

Case V.—George N., æt. five and a half years. I. P., 4, 20. Natural labor, never had convulsions. Whooping-cough at four and a half years. Christmas, 1883,

[1] Erb: Virchow's Archiv, Bd. lxx.

[6] Diseases of the Nervous System, vol. i.
[7] Revue men. des Maladies de l'enfance, 1883–84.
[8] Revue médicale de la Suisse romande, 1887.

began to get restless and uneasy. Was treated for worms, and passed some. Then became weak in the legs. The right leg first became weak, then in January, 1884, the left. The weakness steadily increased. Now the legs are rigid; spastic contraction of muscles of feet; talipes equinus; walks on toes. Is bright. Reflexes increased. No special disease.

Case VI.—Robert G., æt. four years and nine months. M. 6, 48. Only child. Born with instruments, cried for eight hours steadily after birth. In twelve hours a large lump formed in left occipital region. This was lanced and a clot of blood removed. Intelligence good up to fifteenth month. At two years of age said to have had tubercular meningitis. Intelligence impaired ever since. Never had a convulsion. Has a depression at anterior fontanelle, which has a hard base. Says about a dozen words, not particularly fretful. Knee-jerk +. "Lead-pipe" leg; both legs nearly equal in stiffness; no wasting. Progresses by lifting his weight on his arms and throwing his body forward; cannot walk. Arms are strong. Nystagmus present. Phimosis. Teeth are in a state of decay and discoloration.

Case VII.—Frank W., æt. six years. M. 6, 100. A large baby, born with instruments, very long labor. Only child. Mother contracted syphilis six weeks before childbirth, and had a suppurating bubo. Began to walk at eighteen months, but never walked well, always stiffly. Teething a little tardy. Improved in walking till two years ago, when he had several spasms in rapid succession for twenty-four hours, which left him weak. The spasms came on in A.M. about 3 o'clock, did not gain consciousness until 5 P.M. Had much fever; was ill a week. Talked and walked more since the spasms. Has had slight spasms since. Last May had a series of very severe spasms. No stiffness in arms. Legs both spastic, toes turned in. Falls often. Has a very peculiar stiff gait, toes on ground; some incoördination in hands, particularly the left; picks up objects with difficulty; fingers very clumsy. Stiffness of legs most in extension. Feet extended. No nystagmus. Has headache at times. Knee-jerk + on both sides; no clonus. Slobbers a great deal. Does not talk well; says many words. A slight internal strabismus. Biparietal diameter, five and a quarter inches; occipito-frontal seven inches; circumference nineteen and seven-eighths inches.

Case VIII.—Stella H., æt. six years. I. P. B., 73. Never had fits; sickly from birth; no note as to labor. Had a fall at twenty-two months. *Status præsens:* Limbs well developed. At times limbs limber, but often rigid. Leg flexed, toes turned very much in. Can move legs, but cannot stand without assistance. After some effort rigidity is overcome. Arms normal. Electro-muscular contractility normal.

Case IX.—Mamie McD., æt. three years and two months. M. 7, 75. Mother died of phthisis. Born at seven months, no instruments used, labor natural. Always weak; measles three months ago; very severe spasms and crying spells, unconscious fifteen to thirty minutes. Can stand alone for a minute; can walk when supported, cross-legged progression and walks on tiptoe. No special stiffness except when walking. Knee-jerk + +. No ankle-clonus. Ankles inverted; movements of hip-joints normal. Hands not affected. Has night terrors. Intelligence good. No nystagmus. After five months treatment much improved.

Case X.—Violet M., æt. one years and four months. I. P. 4, 46. First child in twenty-three years of married life. Two miscarriages. Labor natural and quick. Child weighed four pounds at three and a half weeks. Fed on bottle. Cholera infantum. No fever, no convulsions. The hands and arms are thin and never have developed well. Motion with them is very much impaired; difficulty in grasping or holding an object. Can walk with difficulty. Head brachycephalic. Intelligence poor. Knee-jerk +. February 15, 1888, is four years old. Has not been able to sit alone; cannot walk. Can say a few words, "papa" and "mamma"; understands everything; looks bright; has intelligent smile. Bad tempered; cries a good deal; dribbles much. Head: bi-parietal diameter, five inches; occipito-frontal, five and three-quarters inches; circumference, seventeen and three-quarters inches. No squint; no nystagmus. Teeth decayed. Had a convulsion last winter. The mother says that the child is like a *rag*. Arms flaccid; hands open; cannot pick up things; muscles ill-developed; a little stiffness of right arm. Legs extended, stiff, moves them about; feet extended, bent with difficulty. Gets very stiff at times, could almost be lifted by the legs. Plantar reflexes good. Sensation good.

FIG. 1.

Position of child in walking.

Case XI.—Joseph J., æt. twenty, colored. Sent to the Infirmary from a distance, and no history could be obtained except that his parents are healthy and that the present trouble had lasted from infancy. Patient is a well-grown lad, and has been accustomed to help at farm work. He is weak-minded, and cannot give a very satisfactory account of his past condition. He has an intelligent looking face, forehead is low. Speech is imperfect, clips the words, and it is often hard to understand him. He has not much education; can read a little. The arms are well developed; uses the hands and fingers well. The legs are muscular, of equal length. When recumbent he can flex them at the knee and hip-joint, though they are somewhat stiff and there is adductor spasm. He walks with a spastic gait, the legs stiff, the thighs adducted and the toes kept close to the ground. The legs cross at each step, as shown at Fig. 6. The entire foot is placed on the ground. The arms are used to maintain the balance, and the body surges from side to side with each step. The knee-jerk is much increased, the ankle clonus can readily be obtained; superficial reflexes also increased.

The condition of the legs in these cases is practically identical with that in the spastic biplegias, and there are instances which link the two groups together. Thus, in Case II. there was inability to use the hands properly and the right arm at times became stiff, and in Case X. the elbows were occasionally stiff, though at the examination there was no trace of it.

That in spastic paraplegia the cerebrum is less profoundly affected is shown by the greater number of children who are bright and intelligent and who ultimately learn to walk. Of the eleven cases, three were mentally well developed; the others presented various grades of feeble-mindedness. Six could speak plainly; in four articulation was defective, and Case X. could only utter a few words. Only one case had strabismus, and in two nystagmus was present.

In many cases the history was defective. In only three were there difficult labors, two requiring the forceps. The paramount influence of abnormal conditions of birth or of parturition in producing this condition is well illustrated in Little's cases, of which I think twenty-four can be selected as paraplegic. Of these, in twenty-three there was either difficult labor or premature delivery; six were first children. In only one instance were the forceps applied, but we must remember that in the fourth and fifth decades of this century the forceps were not used so often as they are at present. In none of Little's cases did the feet present, a point observed by Ross[1] and others.

The stiffness of the legs may not be noted for some months after birth, but usually on washing and dressing the child the mother notices the rigidity. The child is late in attempting to walk, and then the awkwardness and stiffness of the legs become more evident. When standing the attitude is most characteristic — there is talipes equinus, varying from the slightest raising of the heel to a position in which the child actually stands on tiptoe. The heels are usually everted and the knees approximated, owing to the spasm of the adductors, which, with the gastrocnemii, become hard, tense and prominent. In most cases, owing to the elevation of the heels, the body is supported on the balls of the toes. Fig. 2 represents the foot-marks in Case 9 as the child walked, with the soles chalked on a black surface. In other instances, as shown at Fig. 3, the entire foot may be set down at each step. Owing to the extension of the limb as it is being moved forward to take a step, the toes do not always clear the ground, but drag, so that the shoecaps are usually much worn. The strong adductor action produces a remarkable crossing of the legs, and each foot is dragged over and planted in front of, or even to the other side of its fellow. This is very well illustrated in the figures. When extreme, as in Fig. 3, which is taken from Case XI., the body is thrown from side to side in walking, and the arms are kept apart to help maintain the balance. In some instances the adductor spasm is so great that the thighs rub at each step and one foot is shuffled before the other in a series of extremely short steps. The trousers may be rapidly worn out at the inner aspect of the knees in consequence of the constant friction. In attempting to flex the legs there is marked resistance, which gradually yields, and the limb can be bent, as Dr. Weir Mitchell has expressed it, like a bit of lead pipe. The term "lead-pipe" contraction is often used at the clinics to designate this condition. The adductor spasm may be so extreme that it is impossible to separate the thighs—clasp-knife rigidity. When at rest the spasm may relax, but any attempt at movement or an effort on the part of the doctor to flex the leg will at once induce it. Ultimately there may be constant flexion of the legs, with permanent contracture.

Fig. 2.—Showing spastic gait in Case IX.
Fig. 3.—Illustrating cross-legged progression in Case XI

[1] Loc. cit.

The reflexes are increased. The knee-jerk is almost invariably present, though in very young children it is sometimes not an easy matter to elicit. The ankle clonus, as a rule, is not to be obtained. It was present in Cases I. and XI.

Sensation is not impaired. Trophic lesions were not noticed. The functions of the bladder and rectum are unimpaired.

In brief, the symptoms of this affection in children are almost identical with those of adults, and the earlier writers on spastic paraplegia classed the cases together. Heine long ago expressed the opinion that these cases in children are of cerebral origin, and this is now generally accepted on the following grounds: 1. The frequent coexistence of symptoms indicating cerebral defects, such as idiocy, imbecility, nystagmus and the like. 2. The occurrence of cases of bilateral spastic hemiplegia, in which the paraplegic symptoms are identical with those of tabes spasmodique—cases, moreover, in which the evidence is usually very clear of the existence of profound cerebral disturbance. All gradations are met with, from pure spastic paraplegia with perfect use of the arms, to instances of the most extreme bilateral spasm with or without disordered movements. 3. The paraplegic and diplegic cases present identical histories, and a large proportion of the cases in each group are birth palsies, the result of abnormal parturition. 4. As the diplegic cases have been shown to depend upon symmetrical disease of the motor areas with, in many instances, descending degeneration, the conclusion has not unnaturally been drawn that the paraplegic form was the result of a similar though less extensive lesion. Ross,[1] Hadden[2] and Gowers[3] take this view; d'Heilly[4] thinks that there is not necessarily involvement of the brain, but that it may be a primary degeneration of the lateral tracts.

THE MORBID ANATOMY of infantile spastic paraplegia remains to be worked out. In a tolerably careful review of the literature, I can find but one record of a carefully performed section in a case of this kind. Förster,[5] in a report of the Dresden Children's Hospital, among the spastic palsies, gives the following case: Boy, aged two. No history of the parents or of the delivery. At the age of one and a half years the paralysis was noticed, and he began to use the few words of speech which he had acquired. When seen at about the age of two, the arms were normal, the legs stiff, adductor spasm. When attempting to walk he stood on the outer aspects of the feet with the heels raised. Knee reflexes exaggerated. Intellect feeble. The case appears to have been one of true spastic paraplegia. The post-mortem, by Birch-Hirschfeld, showed a moderate grade of general cortical sclerosis, with slight dilatation of the ventricles. The basal ganglia were normal; no note as to pyramidal tracts on crus or medulla. The cord was firmer than normal, and the lateral tracts presented a gray-white translucent aspect, which was regarded as a descending degeneration, the consequence of brain lesion.

DIAGNOSIS.—The diagnosis of spastic diplegia and paraplegia is usually easy, but there are cases from which they must be carefully distinguished and which, at times, closely simulate them. The condition described by writers on children's disease as *idiopathic contraction with rigidity; tonic contraction of the extremities*, the *contracture* of the French writers is very apt to be confounded with true spastic paralysis and *vice-versa*. The confusion which exists is illustrated in several recent papers, notably those of Onimus[1] and Launois[2] and the thesis of Simard.[3] The majority of the cases reported by these writers belong to the category of spastic paralyses due to cerebral disease.

The chief differences between these conditions may be thus tabulated:

Pseudo-paralytic rigidity.	*Spastic paralysis: di- and paraplegia.*
Follows a prolonged illness. Is often associated with rickets, laryngismus stridulus and the so-called hydrocephaloid state.	Usually exists from birth. History of difficult labor, of asphyxia neonatorum or of convulsions.
Begins in hands as carpo-pedal spasm; often confined to hands and arms.	Arms rarely involved without legs, and not in such a marked degree.
Spasms painful and attempts at extension cause pain.	Usually painless.
Intermittent and of transient duration.	Variable in intensity but continuous.

The history, the limitation in many instances to the arms, the existence of rickets or other constitutional disturbance renders clear the diagnosis. The spasm in idiopathic contraction may be extreme, the arms adducted, the forearms strongly flexed and the hands clenched on the chest. In none of the cases of spastic diplegia have I met with such inflexible rigidity of the arms as existed in a rickety child which I saw with Dr. Major, of Montreal. From tetany, which in children is closely related to the carpo-pedal spasm, and occurs under similar conditions, the distinction would rest largely on etiological considerations. In early life the association with rickets and diarrhœa, and the greater involvement of the upper extremities are features of tetany,

It must not be forgotten that tumors of the pons and of the cerebellum may produce a bilateral rigidity when the motor paths are involved or compressed. Tubercular growths of the cerebellum seem specially liable to induce this symptom. In the Gulstonian Lectures for 1886, Sharkey[4] reports four cases, in each of which the tumor occupied such a position that it compressed either pons or medulla.

A CASE OF LAPAROTOMY AND INTESTINAL SUTURE FOR GUNSHOT WOUND OF THE ABDOMEN: DEATH FROM ACUTE PERICAROITIS.

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO, BUFFALO, N. Y.

ON the 6th of March, 1888, I found myself in Bradford, Pa., on a semi-professional errand. On leaving the train, I was accosted by a friend and urged to hasten at once to one of the banks, where the cashier had been assailed by a masked robber.

I lost no time in proceeding there, and, on arriving, found a gentleman, thirty-two years of age, lying on a mattress in a rear room, and learned that he had been shot completely through the body. Several physicians were already in attendance, and, invited by them, I made a casual examination. I found that the bullet had passed back of the middle plane of the body, just below the false ribs. The wound of entrance was just below the margin of the liver, and that of exit in a corresponding position on the left side, a little nearer the back. When I first saw the man he exhibited a severe degree of shock. Stimulants were freely administered, and he was conveyed to his house by those in attendance. He was placed, for the time being, under my care. I could not but conclude that the intestines had been wounded, and could only advise an exploratory laparotomy. I had with me only my ordinary pocket-case, being utterly unprepared for any such operation. From several of my professional friends in Bradford I borrowed other instruments, sufficient for the necessities of the case. At the drug store I had sponges prepared hastily and silk sutures boiled, and in various ways, as best I could, I prepared for the operation.

The patient had been injured at eleven o'clock in the forenoon; at about three the operation was begun. In the meantime he had rallied well from the shock, and was urgent that the operation should be undertaken. I was assisted by Drs. Nichols, Murdock, Van Scoy, Freeman and others, and most of their professional brethren were present. Incision was made in the middle line, chloroform being the anæsthetic. There was a good deal of blood in the cavity of the pelvis, to remove all of which I had to prolong the incision downward and to lift out all the pelvic viscera. There was no injury to any of the pelvic contents. Exploring higher, I had to extend my incision well toward the sternum, and then found that blood was trickling from some injured point well up toward the diaphragm. After long, careful and diligent search, I found a perforation in a loop of small intestine up behind the colon. There was no tendency to eversion of its mucous lining, so I closed it with a Lembert continued suture of fine silk; but the bleeding did not come from this point. On exploring further, it was only after lifting up the stomach that in a neighboring concealed loop I found another perforation with eversion and a long rent along the mesenteric border. These were also closed with Lembert sutures, but with great difficulty, since they lay so deeply, and since the mesentery was so short. After careful examination, I could find nothing more in the abdominal cavity; so I closed the abdominal wound with numerous silver sutures. The wounds of the abdominal parietes I irrigated and drained with very small rubber tubes, and closed with an antiseptic, occlusive dressing.

The operation altogether consumed about one hour and forty minutes. It was of necessity longer than would have been the case had the conveniences at hand been better. The patient rallied from the shock, was given morphine hypodermatically, and became comfortable through the night. He was only disturbed by belching of gas, which occurred frequently. The next morning his temperature was 99¼°, his pulse 110 and his general condition most satisfactory. My business taking me to an adjacent town, I did not see him again until 2 P. M. of the second day. I learned, however, from Dr. Nichols, in whose immediate care he remained, that late the previous evening his pulse began to fail and his temperature to rise. At 1 A. M. he evidently began to sink, and toward morning became unconscious. There had not been any distention of the abdomen, and his pulse did not present the usual features of the pulse of acute peritonitis.

When I saw him at 2 P. M. he was comatose; his pulse scarcely perceptible. The abdomen had shrunk rather than distended, so much so that his dressing seemed a little loose. On placing my ear over the heart, a very loud pericardial friction sound was heard. This was so loud, in fact, as almost to obscure the other cardiac sounds; but he was beyond help and died at 3 P. M., fifty-three hours after the injury, and forty-seven hours after completion of the dressing.

A partial autopsy was made the next day by Drs. Nichols and Straight. They informed me that the wounds we had sewed were found perfectly united, that no leakage had taken place, that in some places the stitches were covered out of sight by plastic lymph. Only slight local peritonitis was found, and the long incision in the abdominal wall had healed by first intention. There had been no hemorrhage, and altogether everything in the abdomen was in as satisfactory a condition as could be expected or desired. The thorax was not opened; consequently nothing can be told about the pericardium.

Here was a desperate case of gunshot wound of the intestine with operation performed under trying circumstances, without adequate facilities, and death occurred from a most unexpected complication. That acute pericarditis is an occasional result of surgical conditions of greater or less magnitude is a fact not unknown, though we are still utterly in the dark as to its etiology. In the case at hand, for instance, time had not elapsed for any septic complication, nor was there the slightest evidence of sepsis, either clinically or post-mortem. Various authors on diseases of the heart are peculiarly reticient on this subject, and the case seems of interest, as much on account of its termination and the cause of death as for any other of its peculiar features.

THE PHYSIOLOGY OF THE NOSE.

By F. H. BOSWORTH, M.D.,
PROFESSOR OF DISEASES OF THE THROAT IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

Popular conception of the nose, from time immemorial, has regarded it mainly as the organ of the sense of smell. This view has, I think, been accepted by medical observers up to comparatively recent

times. The ancients believed that respiration was for the purpose of cooling the blood. Helvetius, in 1729, supporting this view, adduced as an argument in its favor, the fact that the area of the pulmonary vein was larger than that of the pulmonary artery. In 1823, Friederich Hempel[1] asserted that the air was heated in the lungs, making no reference to the nose or mouth as bearing part in this function, regarding the nose as an organ to test the quality of the inspired air, before it passes into the lungs. In 1829, Magendie[2] says, "By successively traversing the mouth, nasal cavities, pharynx, larynx, trachea and bronchi, the inspired air becomes of a similar temperature with the body. . . . . The inspired air is charged with vapor which it carries away from the mucous membrane of the air-passages, and in this state always hot and humid, it arrives at the pulmonary lobules." In the same year, Adelon[3], making no mention of the functions of the nose in respiration, speaks of the moisture of the expired air having its sole source in the lungs. In 1844, we find Dunglison[4] making the following statement: "In passing through the mouth, nasal fossæ, pharynx, larynx, trachea and bronchi, the inspired air acquires pretty nearly the temperature of the body." As early as 1845, however, we find appearing in medical literature, evidence of the recognition of other and important functions as belonging to the nasal chambers, independent of the other portions of the upper air-tract. The first evidence of this I find given by Vierordt[5], who, I think, was the earliest to emphasize the fact that the air is raised in temperature in passing through the nasal chambers, thus recognizing the fact that the other portions of the upper air-tract contribute no part in this important function.

In 1864, we find Nestor Gréhant[6] investigating this subject experimentally. His apparatus consisted of a glass tube containing a thermometer, through which the expired air was made to pass by inserting the tube in the mouth. To protect the thermometer from the temperature of the surrounding air which might thus vitiate the experiment, the tube containing it was enclosed within a second tube, and the space between was filled with cotton.

Gréhant found that with the temperature of the room at 12° C. (53.6°F.), and the patient breathing seventeen times per minute, inspiring through the nose, that the temperature of the air expired through the mouth and apparatus was 35.3° C. (95.5° F.). If, instead of inspiring through the nose, the end of the tube within the mouth was closed with the tongue, and inspiration was performed through the mouth and expiration through the tube, then the temperature of the expired air was only 33.9° C. (93° F.). Although, as will be shown further on, these results are erroneous, the investigation goes to show that, even at this time, the importance of the nose as an organ of respiration was beginning to be recognized.

In a second series of experiments, Gréhant showed that the expired air was saturated with moisture at a temperature of 35° C. (95° F.) and not at 38° C. (100.4° F.) as Valentine had before stated. The error had been made on account of the momentary cooling of the surface of the hygrometer by the expired air: by correcting this error of experimentation, by enclosing the polished face of the hygrometer so that the expired air should not momentarily cool its face, the true result was obtained.

Subsequent to this we find such standard works on physiology as Dalton and Foster making no mention of the fact that the air is warmed and moistened within the nose and mouth before entering the lungs. Flint,[1] however, writes as follows: "The vapor in the expired air is derived from the entire surface which is traversed in respiration, and not exclusively from the air-cells. The air which passes into the lungs derives a certain amount of moisture from the mouth, nares and trachea. The great vascularity of the mucous membranes in these situations, as well as of the air-cells, and the great number of mucous glands which they contain, serve to keep the respiratory surfaces constantly moist. This is important, for only moist membranes allow the free passage of gases, which is, of course, essential to the process of respiration."

Rosenthal[2] claims that air is already warmed and saturated when it reaches the alveoli.

These functions, however, are attributed to the nose in a somewhat adventitious manner, and the general view seems still held that olfaction is the main function of the nasal mucous membrane. Even as late as 1878, we find Remy[3] alluding to the nose as the organ of olfaction, and directly stating that its other functions are purely secondary and adventitious. Remy first states that the watery secretion of the nose is for the purpose of moistening odorous particles, by which they are rendered sensible to the olfactory nerve. His exact language is as follows: "Cette membrane forme l'extrémité supérieure des canaux respiratoires mais, ce n'est jos là son principal but. Cette muqueuse fait partie constituante d' un organe des sens, et ce n' est qu' accessoirement qu' elle sert à un autre usage qu'a la function sensorielle."

An additional function of the nose in phonation was first suggested by Helmholtz,[1] in his beautiful theory of overtones, and subsequently more specifically elaborated upon by Gordon Holmes in his admirable work on the voice.[2] That this conception of the physiology of the nose is an imperfect one and unsatisfactory, I think very emphatically impresses itself upon anyone who has made special study of these chambers in pathological as well as physiological conditions.

The nose undoubtedly possesses a threefold function, in olfaction, phonation and respiration. But that the function of olfaction is the prominent one, I think, is based on entirely incorrect views. The great and important function of the nose is as an organ of respiration, the other functions being entirely secondary.

As we know, the olfactory nerve is distributed in the mucous membrane lining these chambers, but this location is, to an extent, adventitious. Nature found the most convenient place for the distribution of this nerve at the entrance of the air-passages, where it should receive the first impact of odorous particles floating in the current of inspired air. These filaments of the olfactory nerve might have been located in the roof of the mouth, but we easily see how such a location would subject this delicate membrane to great injury on account of the other functions necessarily performed in this cavity. Hence we find the olfactory nerve distributed in the mucous membrane lining the upper and smaller portion of the nasal chambers, where it is thoroughly protected from injury, and deeply sequestrated and walled in, as it were, by its bony surroundings. The function of the nose in phonation needs no special reference. We all recognize the fact that a peculiar resonance and richness of tone of the human voice is largely dependent upon vibration of air in these chambers, as is demonstrated by the fact of this resonance disappearing when the nasal passages are occluded.

It is as a very important, perhaps the most important, and certainly the most intricate portion of the respiratory tract that the nose possesses the highest interest to us. That greater stress has not been laid on this function by writers and observers has always been something of a surprise to me, and yet a careful search of our literature fails to reveal any such recognition until within the last few years.

In a paper read before the American Climatological Association, May 28, 1885, on "Hay Fever, Asthma and Allied Affections,"[3] I first gave somewhat in detail certain views in regard to the respiratory function of the nasal chambers, which subjected me to considerable adverse criticism. All that I then stated I still adhere to, and believe the views there advocated to be entirely correct. The importance of this communication, I think, cannot be overestimated, and I therefore quote in full the views there laid down:

"The normal function of the mucous membrane is to secrete mucus, and only in such quantities as are sufficient to keep the membrane in a soft, moist and pliable condition. Any excess of this amount becomes a morbid secretion. Normally, nasal mucus is composed of 93 per cent. of water and 7 per cent. of solid matter. Robbed of a small portion of this water, it becomes thick, inspissated and unhealthy. Now, as we know, every breath of air that passes through the nasal chambers and reaches the passages below must become surcharged with moisture; otherwise it would rapidly exert a deleterious influence on the mucous membrane of the air-passages beyond in robbing them of their moisture, and so rendering their mucus thick and inspissated. It is estimated by physiologists that in the course of twenty-four hours about five thousand grains of water are taken up by the inspiratory current of air, in its passage through the respiratory apparatus. If, in other words, the humidity of the inspired air be compared with that of the expired air, it will be found that, in addition to the other changes as regards carbonic acid and oxygen, the inspired air will have gained five thousand grains of water. Now, I think I am safe in saying that, if five thousand grains of water were extracted from the mucous membrane of the bronchial tubes and air-cells in the course of twenty-four hours, the result would be complete destruction of their function, to such an abnormally dry condition would they be reduced; for, as we know, in each act of respiration the inspired air reaches only the larger bronchial tubes, and the source of moisture, therefore, of the inspiratory current cannot be from the smaller bronchial tubes or air-cells. We are, therefore, forced to the conclusion that this surplus of five thousand grains is taken up by the inspiratory current during its passage through the nasal chambers, and is still retained by it as it makes it way out through the air-passages, for the only source from which this amount of water could be taken up is the nasal mucous membrane. Certainly from no other mucous membrane of equal area in the body is it possible that such an amount of water could be secreted in twenty-four hours in health. Now, the mucous membrane of the air-passages is endowed with no especial apparatus for the secretion of water; the only secretory apparatus with which it is endowed is in the mucous glands, which secrete mucus alone.

"In the nasal mucous membrane, however, we find an apparatus capable of furnishing this water, and this is the so-called erectile tissue of the turbinated bodies. The necessity for some such apparatus I need not refer to, further than to say that it is absolutely necessary and essential, for the integrity of the lower air-passages, that the air which reaches them should be so far charged with moisture that they should not be robbed of any of their secretion. Especially is this true in a variable climate like ours, in which so great changes occur, characterized by excessive humidity or absolute dryness of the atmosphere.

"This, then, is the great and prominent function of the nasal chambers, so to prepare the ingoing current of air that it shall exercise no injurious influence on the mucous membrane of the passages below. It has always seemed to me that this great respiratory function of the nasal chambers has been to an extent overlooked in regarding the nose as an olfactory organ, for whereas impairment or loss of the sense of smell is but an incon-

[1] Die Lehre der Tonenfindungen als physiologische Grundlage für eine Theorie der Musik. [Ellis translation, p. 40.]

[2] Vocal Physiology and Hygiene. Gordon Holmes. London, 1879 p. 129.

[3] N. Y. Med. Journ., April 24 and May 1, 1886.

venience, and not dangerous to the health, the impairment of the respiratory function of the nasal cavities involves very serious danger. Thus the nose as a respiratory organ becomes infinitely more important to us than as an olfactory organ.

"As before stated, the nasal chambers contain no glands which secrete other than mucus. There are no serous glands. The mechanism, however, by which the water is poured out into the nasal chambers, and the ingoing current thus surcharged with moisture, is in this so-called erectile tissue. The watery constituents of the blood transude the mucous membrane, and appear on the tortuous surfaces and passages of the cavity. Now, unless the bloodvessels underlying a membrane called upon for this duty were very large and very numerous, they would be inadequate to supply this large demand. Nature, therefore, has furnished the membrane in this region with such an abundant supply of large, tortuous vessels that they assume the appearance of erectile tissue, and thus have given rise to this erroneous idea as to their function suggested by the name erectile tissue. Were the bloodvessels in this region of the same calibre and capacity as those of other portions of the air-tract, it is easy to understand how the extraction of so great a quantity of water would soon render the current sluggish by its greater consistence, and so completely arrest the function which they were designed to subserve. In addition to this large blood-supply there must be, of course, some delicate mechanism by which this function is regulated. This control is exercised by the vaso-motor system of nerves. So delicately must this be arranged that the transudation of serum must accurately adapt itself to every existing atmospheric condition. To-day, for instance, with air saturated with moisture, the turbinated vessels must be so far kept in control by the vaso-motor nerves that no serum escapes. To-morrow, again, with an almost absolutely dry atmosphere, under the action of the vaso-motor nerves, the blood control is unlocked, as it were; the turbinated vessels are so charged with blood that the current becomes active, and the amount of serum poured out on the mucous surface of the nasal cavity is such as thoroughly to saturate the ingoing current of air with moisture, and still not impair the consistence of the blood flowing through the vessels. This control must be so delicately exercised as to meet not only daily, but even momentary changes in the humidity of the inspired air. It is easy to see, therefore, how great the demand must be upon the vaso-motor nerves which regulate the calibre of these bloodvessels, how constant the watchfulness which controls this exosmotic action, and therefore how easily any impairment of this function might occur."

These views were based on the result of many years of clinical observation of this membrane both in health and disease.

From an anatomical point of view, it is difficult to understand why nature should have placed in these passages the somewhat intricate and complex mechanism which we there find, unless it was designed to subserve some important purpose. That this purpose is not connected with the function of phonation or olfaction I think cannot be questioned. We must then conclude that its design is connected with the function of respiration. I think we can more clearly reach a conclusion in the matter by a reference to the anatomy of this membrane.

In brief, we find the nose consisting of two wedge-shaped cavities, extending from the nostrils to the posterior nares, their inner wall consisting of the smooth face of the vomer and cartilages of the septum; their outer wall being formed by the superior maxillary, ethmoid and palate bones. Imposed upon this wall, we find the three so-called turbinated bones, scroll-shaped bones, which are designed to increase the surface over which the mucous membrane is distributed, dividing the cavity, as anatomists tell us, into three passages, which are mainly nicely drawn distinctions of an anatomical character. The floor is made up of the smooth surface of the palate and superior maxillary bones. These bony cavities are lined by a mucous membrane. Now, a mucous membrane is pretty much the same thing wherever you find it. It is simply a typical membrane, which is found lining all the cavities of the body which communicate with the external world. As a necessary part of the design of these cavities, their lining membranes must be soft, moist and pliable. In order that they shall possess these three properties, nature has embedded in their tissues certain glandular structures which secrete mucus. This mucus is to be regarded simply as a lubricant, and nothing more. No mucous membrane in the body is endowed with secreting structures more than sufficient to pour out on its surface just sufficient mucus to lubricate the membrane and keep it soft and pliable.

If there are any exceptions to this rule, they are merely such exceptions as are demanded by particular localities, as, for instance, in the vault of the pharynx and between the two pillars of the fauces we have large masses of glands which pour out an abundant supply of mucus, whose function is to lubricate the bolus of food, and facilitate its passage into the stomach. But aside from these rare exceptions, no mucous membrane is endowed with the power of secreting but a limited supply of mucus. Nor does nature ever call upon it to do more. We have here, then, in the nose, so far nothing which renders it capable of subserving any special function in the economy; simply a bony cavity lined with mucous membrane. In the upper part of this cavity we find distributed the nerve of olfaction. Here we find an additional function, which demands for its healthy action nothing further than a moist membrane, which will afford protection and distribution for the olfactory nerve.

In addition, however, to the parts already described, there are found *beneath* the surface of the mucous membrane, on the faces of the lower and middle turbinated bones, large plexuses of bloodvessels, the turbinated bodies, which have figured so extensively in our literature of the last fifteen years, and have been the subject of so much speculation and discussion. This mass of bloodvessels was recognized by anatomists in the last century, but in a vague and somewhat indefinite way.

According to John Mackenzie,[1] the spongy character of this tissue attracted attention as early as 1656, being mentioned by Rolfinc.[2]

Schneider[3] recognized it as containing vascular tufts, but did not recognize its cellular structure. This was first mentioned by Ruppert.[4]

Duverney[5] gives a more detailed description, and states that the membrane can be inflated by a blowpipe inserted into the veins.

The first to announce distinctly its true erectile nature was probably Cruveilhier,[6] who describes it as a very vascular and truly erectile tissue, and demonstrates its structure by the injection of mercury through the lymphatics.

The first careful anatomical investigation of this tissue was made by Kohlrausch,[7] who described what he supposed to be large venous sinuses existing in the deep layer of the membrane. Such a plexus had been previously referred to by Hyrtl, as acknowledged by Kohlrausch. It was subsequently claimed as an independent discovery by Kölliker.[8] In 1873, Bigelow[9] made some very careful observations of these structures, in which he demonstrated the existence of erectile tissue. It should be stated, however, that Kohlrausch[10] in his investigations had shown the existence of loops or helicine arteries, which at that time were recognized as an anatomical condition characteristic of erectile tissue. Kohlrausch's investigations were made in the moist tissue. Bigelow inflated the moist tissue with a blowpipe inserted into the veins themselves, as had been done already by Duverney.[11] and made his sections after the preparations had been allowed to dry. Bigelow's demonstration showed a very beautiful, spongy tissue. These observations were subsequently very nicely confirmed by Ischwald.[12] All these investigators asserted that this tissue was erectile tissue, their conclusions being based apparently on anatomical study alone.

Zuckerkandl,[13] however, whose classical work on the anatomy of the nose is the standard authority to-day on this subject, has made an exhaustive anatomical study of this membrane, in which he describes the mucous membrane covering the turbinated bones as consisting of connective tissue, the upper surface covered with flat epithelium, the deep layer forming the periosteum of the turbinated bones. Between these two layers we have abundant lymph tissue, and possibly lymph glands, although these have not been definitely made out. The tissue covering the turbinated bones is studded here and there with tubular mucous glands, many of which extend completely through to the periosteum. Within this lymphoid structure we have abundant venous plexuses, to which he gives the name "Schwellkörper" (swell bodies). About the venous plexuses the unstriped muscular fibre is abundantly distributed. The definite localization of the venous plexuses serves to distinguish this tissue from true erectile tissue, such as is found in the corpora cavernosa of the penis. The arterial supply is derived from the spheno-palatine artery. The capillaries are divided into three sets, one set being distributed to the periosteum, the second to the glands, the third to the surface. The capillaries distributed to the surface form loops which empty into veins, together with the superficial gland capillaries. The deeper gland capillaries and those distributed to the periosteum, pass into the veins, forming the so-called Schwellkörper, and the blood is then conveyed by venous channels in the periosteal surface of the membrane to five distinct plexuses, one going to the veins of the face, the second to the veins of the cranium, the third to the orbit, the fourth to the soft palate, and the fifth to the hard palate. These Schwellkörper are distributed, according to Bresgen.[1] quoting from Zuckerkandl's anatomy, as follows: One over the lower turbinated body, one along the border of the middle turbinated body, and one at the posterior extremity of each of the turbinated bodies.

We find, therefore, the nasal cavity containing this most intricate and delicate apparatus, which is designed to subserve the function of the already described serous exudation. The special method by which this serous transudation takes place we are scarcely ready to describe, though a very important suggestion comes to us from the notable observation of Chatellier.[2] He describes certain minute canals, running at right angles to the mucous membrane, penetrating to the lymph channels. Chatellier makes the suggestion that these canals serve the purpose of serous channels. The question arises, Whether Chatellier's canals may not be the tubular mucous glands of Zuckerkandl?

As before stated, when I first described this great respiratory function of the nasal mucous membrane, the observation met with considerable opposition

and criticism.[1] Dr. Sherwell, of Brooklyn, took issue with my statements as something entirely novel, radical, and, as not having been based on physiological research and clinical observation. Sherwell cited cases of complete nasal stenosis, with habitual mouth breathing, in which the pathological lesions of the lower air-passages were not observed. This opens up rather a large question. The old physiological observation on the difference between the inspired and expired air, in which it is claimed the expired air gains a large amount of moisture in respiration, is, I believe, invariably made by the insertion of the tracheotomy tube in one of the lower animals.

Now, there is this to be said with regard to Sherwell's criticism: When any radical change is effected in the economy, by which extraordinary demands are made on an organ, that organ is generally found equal to the emergency. Probably there is no organ in the body which is not capable of doing twice the work which nature usually demands of it. If one kidney is extirpated, the other kidney is equal to the double duty, and so of other organs. When a tracheotomy tube is inserted, nature makes an effort to accomplish the normal respiratory process, and for a time succeeds. Air, containing a fixed amount of moisture, entering the lung through the tracheotomy tube, comes in contact with a cavity filled with air in a state of saturation. Necessarily, by an invariable law of nature, a portion of that moisture is taken up and conveyed to the outer world in the expired air, fulfilling the requirements of the old physiological experiment. But this process cannot go on indefinitely. The moisture of the expired air is acquired, evidently, by robbing the mucous membrane of the bronchial tubes, with the subsequent result of inspissated mucus, bronchial irritation and bronchitis. Sherwell was quite right in the assertion that my observations were based on no physiological experiments; no definite data were given. They were based entirely on clinical observation of the respiratory process, both in health and in disease, continued through a number of years. Since Sherwell's letter was published, however, I find my observations confirmed in a very striking manner by Aschenbrandt's[2] exhaustive experiments, in which data of a sufficiently definite character are given to establish all of my conclusions.

Aschenbrandt's experiments were conducted in the Physiological Institute of Professor Flick, of Wurzburg, and in the following manner: An air aspirator, with a capacity of five litres (five and a quarter quarts), is attached to one of the nostrils by means of a glass tube in which a thermometer is fixed in such a manner as to register the temperature of the air immediately upon its exit from the nose. One litre (quart) of air is passed every six seconds, each experiment being finished in thirty seconds. In a large number of experiments Aschenbrandt found, that with the temperature of the air in the room varying from 8° C. (46.4° F.) to 12° C. (53.6° F.), the temperature of the air as it passed from the nose did not vary from 30° C. (86° F.). Now the temperature of the expiratory current in ordinary respiration is 30° C. (86° F.), which shows conclusively that the warming of the air in respiration is done exclusively by the nose.

Experiments were also made as to the amount of moisture in the expired air, and were conducted with the same apparatus. He found that each five litres (five and a quarter quarts) of expired air contained 0.18 gram (2.77 gr.) of water, which constitutes complete saturation, and furthermore that the whole amount withdrawn from the body in twenty-four hours was 500 grams (7715 gr.), and that the source of this, therefore, was in the nose. A still further conclusion was drawn from these experiments, that all mechanical dust is completely arrested during inspiration, and is deposited on the moist surfaces of the nasal membrane.

Subsequent to Aschenbrandt's observations, Kayser[1] made a series of investigations in the same line. He made use of the same aspirating bottle as Aschenbrandt, and the thermometer tube fitted into the nostril is essentially the same. In Aschenbrandt's investigations, however, the upper pharynx was not shut off, and hence warm air could be drawn from the mouth out through the nose, by the aspirator, and thus vitiate the experiment. To obviate this source of errors in Kayser's experiments the palate is held up by a spatula, after the application of cocaine, and the upper pharynx and nose shut off completely from the lower pharynx and mouth. The temperature of the air after passing through both nostrils, five litres (five and a quarter quarts) in thirty seconds, was found to be the same as in Aschenbrandt's experiments, 30° C. (86° F.), when the temperature of the inspired air was 12° C. (53.6° F.); with external temperature of 0° C. (32° F.) to —4° C. (24.8° F.), the temperature of expired air was 27.5° C. (81.5° F.). If the inspired air was 19° (66.2° F.) to 20° (68.7° F.), the expired air was 32.3° (90.1° F.) to 33.5° (92.3° F.).

For testing the heating power of one nostril, instead of passing a tube through the mouth behind the palate, closing one nostril, and aspirating through the other as Aschenbrandt did, Kayser passes a caoutchouc tube through the inferior meatus of one side, the posterior end of this tube passing beyond the choana; the anterior end was fitted closely into the nostril by means of a rubber cork. The appar-

[1] Pflüger's Archives, vol. xli. pp. 127–47, 1887.

atus for aspiration and determining the temperature was then fitted to the other nostril. It is easy to see that by this means the heating effect of only one nasal cavity was obtained. The palate was held up as in the preceding experiment.

In this experiment, Kayser differs somewhat from Aschenbrandt, for while Aschenbrandt found that the air was heated just as much in passing through one nasal cavity as through both, Kayser found that it was heated about 0.5° (0.9° F.) less. Variations in external temperature made the same difference in the expired air as in the first experiment.

Kayser also performed a series of experiments for the purpose of finding how much the air was warmed in oral breathing. A caoutchouc tube was passed through the inferior meatus of one side to the choana, and the opposite nostril closed with the finger. The tube containing the thermometer was fitted into a cork, and held between the lips. The aspiration was then performed in the usual way. It was found that the air was heated almost half a degree less than in passing through both nostrils.

For determining the amount of moisture in the air after its passage through the nasal chambers or mouth, the thermometer tube was replaced by a U-tube containing pumice stone and sulphuric acid. The increase in weight of the tube at the end of each experiment enabled him to calculate the amount of water contained in the expired air. As a result of these experiments he found that in its passage through the nose or mouth the air was completely saturated with moisture.

The above experiments, as originally suggested by Aschenbrandt, were intended to approximate as nearly as possible the conditions of normal respiration, the tidal air being taken as five hundred cubic centimetres, and respiration rate as twenty. In thirty seconds, then, five litres (five and a quarter quarts) of the air would pass through the respiratory passages. Kayser points out that at least half the time is consumed by expiration and repose, and consequently in the experiment the air has been allowed to remain in the nose and mouth at least twice as long as it does in normal respiration. He, therefore, repeated all of the above experiments, regulating the aspirator so that five litres (five and a quarter quarts) would pass in fifteen seconds instead of thirty seconds. He found, however, that this increased rapidity did not notably influence the result, either with reference to temperature or saturation.

To simulate as nearly as possible the conditions found in the trachea and bronchi, Kayser made use of a glass tube of such a length and diameter that its area was about equal to that of the trachea and larger bronchi. This tube was lined with filter paper saturated with water. A thermometer was fixed in this tube so that its temperature could always be determined, and the temperature was kept constant by enclosing it in a hot-air bath. One end of the tube was left open, the other was connected with the tube containing a delicate thermometer, the same apparatus, in fact, used in the preceding experiments for determining the temperature of the expired air. Here he found that lowering the temperature of the air before aspiration made considerable difference in the temperature of the air after aspiration, and that doubling the rate of aspiration also exerted an influence upon the temperature and moisture of the air after aspiration.

For the filtering out of mechanical dust Kayser claims that Aschenbrandt's investigations are not conclusive, since with the apparatus with which the experiment was made very little dust could get into the nose at all. He consequently improved the apparatus, using a glass globe with three openings. One of these communicates with a bellows used to agitate finely powdered magnesia, the second is open to the air, the third is connected with a glass tube fitting tightly into one nostril. A similar tube connected with the aspirator is fitted to the other nostril. If now aspiration is conducted in the usual manner, and at the same time the dust is agitated by the bellows, Kayser finds that dust can still make its way around into the nostril connected with the aspirator, thus proving that the nose is not a perfect filter for mechanical dust.

Kayser makes the further observation, that when cold air is inspired through the nose, there is a notably increased blood supply in the turbinated bodies, thereby increasing their heating capacity. In this connection he suggests that in tracheotomy the inspired air in summer must be of a temperature of 30° (86° F.) to 35° C. (95° F.), and in winter of 25° (77° F.) to 28° C. (82.4 F.°), and in each case must be saturated with moisture in order not to produce bronchial irritation; the reason being that the bronchial membrane is not endowed with a special apparatus for moistening and heating the air.

It will be noticed that Kayser makes no definite statement as to the amount of moisture poured out by the venous sinuses of the nose in the twenty-four hours. Aschenbrandt, however, makes the statement that the whole quantity of water which the air in respiration draws from the human body amounts to about 500 grams (7715 grains) in the twenty-four hours, and this is taken from the mucous membrane of the nose. This observation, however, was scarcely necessary, when the amount given in my original paper as from twelve to sixteen ounces is the amount given by all physiologists as the amount taken from the lungs. Both Aschenbrandt and Kayser, however, make the definite statement that all the air which passes to the lungs through the nose is in a state of saturation. Of course, saturated air passing in and out of the lungs takes absolutely no moisture from the bronchial mucous membrane.

The proposition is proven beyond question, as previously stated by myself, that the sole source of moisture is in the nose. I think we may declare it as an established truth, that the function of the so-called erectile bodies is serous transudation, and that they are designed to subserve no other function in the economy.

The observers already quoted have made allusion to the fact already generally accepted by physiologists, that the air in passing through the nose is cleansed, in that floating particles of foreign matter lodge against the moist and tortuous surfaces. Probably, however, this is an adventitious function; certainly it is a very unimportant one. I have never regarded the bronchial mucous membrane as subject to any serious danger from floating particles of foreign matter making their entrance with the inspired air. In seeking for a proper function to assign to this falsely called erectile tissue of the nose, the assertion has been made, notably by John McKenzie, that they are designed to swell up and thereby close the nasal passages to prevent the entrance of foreign bodies. This observation, it has always seemed to me, was based on the original mistaken idea that the turbinated bodies are erectile tissue; and, therefore, their function is to become erect. I think it has been demonstrated that these bodies are not erectile tissue. Furthermore, they never become erect in health or disease. Certainly, if nature intended that they should swell out, and thereby occlude the nasal passages to prevent the entrance of foreign bodies, thereby compelling the opening of a far more vulnerable tract through the mouth, nature has been guilty of an awkwardness of design which presents no analogy in the whole human economy.

26 WEST FORTY-SIXTH STREET, NEW YORK.

SOME CONSIDERATIONS CONCERNING THE OPERATION OF VAGINAL HYSTERECTOMY FOR CARCINOMA, ESPECIALLY CERTAIN OBSCURE CONTRA-INDICATIONS.

BY ANDREW F. CURRIER, M.D.,
OF NEW YORK.

REPORT OF AUTOPSY SUBSEQUENT TO VAGINAL HYSTERECTOMY AND INFERENCES FROM THE FINDINGS.

BY WILLIAM H. PORTER, M.D.,
OF NEW YORK.

IT has usually been stated by those whose experience in vaginal hysterectomy has been extensive that, given a case in which the disease (carcinoma) is not so far advanced as to render hysterectomy impracticable, the principal contra-indications are a very small vagina or a very large uterus.

The ten years that have elapsed since this operation came into prominence have been very fruitful ones. Not only have they demonstrated its great advantage over the method by abdominal section, both in respect to the facility with which it can be performed and the less degree of risk as to the immediate results of the operation, but they have also shown that there is a possibility in a certain proportion of cases of removing all the diseased tissue.

Removing diseased tissue, however, is quite different from removing a tendency to disease, and herein doubtless lies the explanation of the early recurrence of carcinoma in many cases in which a most rigid examination of the amputated mass shows that the section has been made beyond the diseased and into the sound tissue. This applies alike to cancer of the uterus and cancer in any other part or organ, and this opinion gains weight from the statements of MacEwen at the discussion on cancer before the Glasgow Clinical and Pathological Society, in 1886 (see *Glasgow Medical Journal*, April to July, 1886). He had observed that in cases of cancer of the lip, in which the amputation was extended quite beyond the apparent limits of the disease, the epithelium of the apparently sound skin, contiguous to that which was evidently diseased, began to show signs of disturbance and irritation before proliferation or infiltration had occurred. It would seem as if there were a kind of epithelial infection, as Rindfleisch believed, though perhaps not in the sense in which he regarded it, which renders permanent recovery, even after the most carefully conducted operations for cancer, so delusive.

In uterine cancer especially one cannot be too confident that even the diseased tissue has all been removed, though the uterus may have been small and perfectly movable, and the history of the patient without especially damaging features. The case which is here recorded will sustain this statement, and, in view of the possibilities, suggests for each case a careful weighing of the argument of Martin and Schauta in favor of complete removal of the uterus, with that of Schröder and Hofmeier in favor of partial removal or palliation.

As to the technique of vaginal hysterectomy, it would seem that the methods of Martin, Leopold and Fritsch, and the recent suggestions of Richelot to secure the broad ligament with clamp forceps, thus saving the time and difficulty of ligating those structures, left little to be desired in this direction. There can be no question that the more rapidly the operation is performed, and the less the quantity of blood lost, the better will be the patient's chances of recovery. It is the rapid and skilful operating of those gynecologists, chiefly Germans, who have published tables of such brilliant successes, that has contributed mainly, in my opinion, to the results which they have had. If this is true, it follows that the operation is destined to be limited to men of exceptional ability as anatomists and surgeons. For such

it is, doubtless, an easy operation, but it can never be to those who are unfamiliar and unpractised in operations in a deep cavity like the vagina.

With regard to the element of time which may elapse between a vaginal hysterectomy and a possible recurrence of the disease, it does not seem to me that the question has been fairly argued by all the opponents of the operation. One point after another of their opposition has, however, been wrested from them. It was first the unusual difficulties of the operation that were urged against it, then the unwarrantable exposure to secondary hemorrhage and dangers of septic infection, and finally it was declared useless because the disease always recurred. If we allow this last charge to include abdominal hysterectomy as well as vaginal, at least one brilliant case can be cited to controvert it; a case which was operated upon ten years ago by Prof. W. H. Freund, and in which, at a recent date, there had been no recurrence. Such a case could fairly be considered cured. There is no doubt, in my mind, that the operation is in very many cases justifiable, and that it will continue to be so regarded if it can offer, as it certainly can, to the large majority of those who are considered proper subjects, immunity for one, two or three years. The constantly improving statistics teach very clearly that we may hope for something even better than this in the near future.

If this operation be compared with that of amputation of the breast for malignant disease, and scarcely any one will question the propriety of the latter, it will be found that the results are favorable to hysterectomy. Martin in his paper before the Ninth International Medical Congress (*loc. cit.*) stated that Küster had, in 1883, reported 778 cases of breast amputation with a mortality of 15.6 per cent., while his own table of 311 cases of vaginal hysterectomy, including the work of Fritsch, Leopold, Olshausen, Schröder, Staude and Martin to the end of 1886, showed a mortality of only 15.1. It will readily be admitted that too much stress should not be laid upon these statistics, for the gynecologists mentioned are among the best in the world, and their work in the field of hysterectomy is the very best that has been done, and merely represents the possibilities of the operation, not what is achieved by the average of those who practise it.

The question of recurrence should not have more influence than it does with those other forms of malignant tumors which deform and disfigure various parts of the body, but especially the head and face. There are few skilful surgeons who will decline to remove such, and yet they present all the objections which have been urged against vaginal hysterectomy. Whatever the skill of the operator, however, I believe there are more limitations to the operation than have generally been laid down. I would not take the extreme position of my friend, Dr. Reeves Jackson, and condemn the operation *in toto* (see discussion on A. Martin's paper on "Vaginal Hysterectomy," *Transactions of the Ninth International Medical Congress*, Section on Gynecology), nor do I think that for so grave an operation Martin's and Schröder's indications are broad enough, namely, that the uterus should be freely movable and sufficiently small, the vagina sufficiently capacious and the circum-uterine tissues without evidence of infiltration to the examining finger.

It is only repeating what has been said many times to state that the examining finger, no matter how well trained, is liable to be deceived in this matter. A case is recalled in which excellent diagnosticians recommended Freund's operation, but when the operation was performed the posterior wall of the bladder was found so infiltrated as to break down like wet paper. Lancereaux has stated that kidney disease always exists in cases of uterine cancer which have attained any extent, and in my own experience I do not remember to have seen a case of advanced uterine cancer in which *advanced* kidney disease did not coexist, as shown by autopsy. I am not aware that any one has yet ascertained the precise or proximate stage of cancer of the uterus when the kidneys become involved.

If we limit the field of the operation strictly to those cases in which it can be demonstrated that the uterus alone is involved, we may rest assured that it will be performed less frequently than it now is, for in the majority of cases the attention of the patient is not called to her condition until severe symptoms occur, and then lymphatic involvement has usually taken place to a greater or less extent. In the case which is here reported it was considered that the disease was limited to the uterus, but, as the pathologist's report shows, it had invaded one broad ligament and the contiguous pelvic lymphatics to a slight extent, but sufficient, no doubt, to have served as a focus for further infection. The contra-indications to which particular attention was to be called will be referred to in the following history, and in the accompanying paper of Dr. W. H. Porter.

The patient was kindly referred to me by Dr. C. E. Bruce. She was a native of France, fifty-four years of age, and ceased menstruating at the age of forty-eight. She had had two children and two miscarriages, at the fifth and sixth months respectively. All her labors had been accompanied by severe hemorrhage. Her last pregnancy was during her thirty-sixth year. A year before she came to me she began to suffer pain after coitus, and at such times there was also a slight serous or sero-sanguinolent discharge. At various intervals during this year there were also rather free hemorrhages. Within two weeks of my seeing her she began to have severe pain in the hypogastrium and frequent desire to urinate. Her bowels were constipated, and straining at stool excited bleeding. The uterus was small and

movable, the cervix being hard and contracted, and free hemorrhage was excited by very gentle manipulation, although the latter caused no pain. A sound could be passed only a very short distance into the uterine canal. The examinations were made in both the dorsal and the lateral positions, and it could not be ascertained that either the vagina or the circumuterine tissues were implicated. In fact, it seemed to be an entirely suitable case for hysterectomy. That operation was performed April 18, 1887, and while I doubt not that it would have proved sufficiently easy for a more experienced operator, it was for me exceedingly difficult, and of very long duration. There are certain delays in a first operation of this character which cannot be foreseen, and in view of such possible accidents as ligation of the ureters, rupture of the bladder and injury to the intestines, it is better to proceed slowly and avoid great risks.

The day following the operation the patient did fairly well, passing only four ounces of urine, however, which contained pus, blood, eight per cent. of albumin and granular casts.

On the second day the urine was more abundant and of better quality, but the stomach began to be rebellious, and the mind unsteady. The temperature did not exceed 100⅓° F., and the pulse was steady at about 100 and of fair quality.

The third night was a very restless one, and the patient was wildly maniacal. Thinking that the symptoms might be due to iodoform poisoning, the wound having been freely dressed with that substance, and the vagina packed with iodoform gauze, I removed the tampon, when the patient at once fell asleep. On awaking, the delirium and restlessness returned, the respiration being markedly irregular and varying between seven and fourteen per minute. The urine was drawn every eight hours, as much as four ounces being obtained at a time, and thus continued during the subsequent twenty-four hours. At 8 P. M., on the evening of the third day, the temperature was 102⅘° F., and the pulse 108 and of fair quality. The patient was quiet, but subsequently became delirious and remained so during the night.

Near the end of the fourth day heart failure came on, and death resulted on the fifth day.

It is not a pleasant duty to relate one's fatal cases, but it seemed proper in this instance, especially inasmuch as a careful autopsy was made, which resulted in the discovery of very interesting conditions. No metastases of the disease were found in the viscera, but the question is very pertinent whether, with such lesions as were present, aside from the cancerous disease, there would be very much hope of performing a successful operation. On the other hand, the lesions were obscure, and certainly were not suggested by the patient's history. Perhaps it is more accurate to say that they were overshadowed by her uterine disease. At all events, the case proves that in forecasting the probable result of an operation of this character, there is room and necessity for more thorough preliminary examinations than are usually made.

In this case the autopsy showed that the heart was not in condition for the strain which was required. Bramwell (*Diseases of the Heart*, Edinburgh, 1884, p. 649) simply records a matter of common clinical observation in stating that "persons whose hearts are fatty bear pain badly, and are unfavorable subjects for severe operations," and Da Costa (*Medical Diagnosis*, Philada., 1884, p. 408) observes that fatty degeneration of the heart is one of those disorders with the anatomical characters of which we are far better acquainted than with their clinical history; also, "there is as yet no sign discovered by which we can positively say that the dangerous disorganization of the muscular fibres of the heart is in progress." The condition of the liver in this case was also unfavorable for a successful issue. The coexistence of the fatty and cirrhotic conditions is interesting, and it is a wonder that the patient's general condition, prior to the operation, was so good with such a combination of lesions.

Dr. Porter considers that the kidney lesions in this case were the principal cause of death (see his subjoined paper), which lesions he thinks were developed subsequent to the operation. May it not be that the fatty and granular changes in the epithelium of the uriniferous tubules formed a portion of the process of fatty infiltration which involved the liver and heart. The weakened condition of the heart-muscle certainly militated seriously against the distributing power, favoring venous stasis; destruction of a large area of liver surface interfered seriously with the metabolic function of that organ, and the imperfect aëration of the blood and oxidation of its oxidizable elements which necessarily resulted, would seem to account for the toxæmia which was probably present as early as the second day, and, from the nature of the conditions, must necessarily become more and more intense.

Under these circumstances the increased labor which was required of the kidneys, which were already weakened by disease, or, at any rate were predisposed to it, could not fail to produce acute inflammatory symptoms, and yet their function was by no means destroyed, for until the last few hours of life they were secreting a not inconsiderable quantity of urine.

Under all these conditions, it cannot be considered strange that the operation resulted fatally. The lesions, in my opinion, were sufficient to contraindicate the operation; but whether one would be able to discover such lesions in any given case, even after the most careful physical and chemical examinations, is a matter which may be seriously doubted.

Necropsy twelve hours after death. Body abundantly supplied with adipose tissue. Rigor mortis marked.

Thoracic cavity. The pericardial sac contained

about one-half ounce of clear, straw-colored serous fluid.

The *heart* was slightly enlarged and infiltrated with fat. The muscular tissue was pale, soft and somewhat granular. The segments of the mitral and aortic valves were the seat of a moderate amount of fatty infiltration, but the valves were free and apparently competent.

The *aorta* was the seat of marked fatty infiltration and commencing atheroma.

The *lungs* were slightly bound to the chest wall, deeply pigmented, congested and œdematous.

Abdominal cavity. The spleen was slightly enlarged and softened. There was no evidence of any hemorrhage into the peritoneal cavity, nor about the stump left by the operation. Everything about the stump indicated the development of a favorable reparative process.

The *kidneys* were enlarged, pale in color and very soft. Their capsules were not thickened or adherent, and the underlying renal surface was perfectly smooth after enucleation. Both the cortical and medullary portions were enlarged and whitish in color. *Microscopic examination* showed the epithelial cells of the uriniferous tubules throughout the kidney to be very much swollen, and their protoplasm filled with minute granular and fatty particles common to a rapidly progressing granular and fatty metamorphosis of the kidneys. The intertubular tissue was swollen and œdematous, but there was no development of new interstitial tissue. A few hyaline, granular and fatty casts were found in the tubules of the Malpighian pyramids.

The few minims of urine removed from the bladder at the necropsy were loaded with albumin and casts.

The *liver* was in an advanced state of fatty infiltration, and there was a parenchymatous metamorphosis of the protoplasm of the hepatic cells, unaffected by the fatty change. There was also a slight amount of interlobular cirrhosis.

Death in this case was due to the rapidly developed parenchymatous metamorphosis of the kidneys which caused a uræmic toxæmia followed by cardiac paralysis.

A careful *macroscopic examination* of the stump of the operation showed that all the ligatures were in position, and had not slipped. A thorough *microscopic examination* of the tissues behind the stump revealed the fact that all the carcinomatous tissue had not been reached by the operation. Marked alveolar spaces irregularly packed with epithelial cells having no intercellular substance were found in the retro-peritoneal tissue. The lymph spaces were also distended and contained epithelial corpuscles, also indicating a general spread of the morbid process.

The results of the necropsy would indicate a successful operation, so far as the operative procedure was concerned, all the growth having been removed that could possibly be reached by the knife. The stump being perfectly secured by the ligatures, hemorrhage had been prevented. There was no evidence of peritonitis, and the stump indicated a favorable reparative process. The chief point of interest, however, was in the rapidly developed parenchymatous metamorphosis of the renal organs (for explanation of the manner in which this change is produced, see Porter *On Renal Diseases*, p. 77, New York, 1887).

It might be well to say, in addition, from a further study of the subject, that in all the fatal cases of a similar nature to this one reported by Dr. Currier, in every instance marked hepatic lesions were found at the necropsy. In those cases in which the urine was carefully analyzed prior to the operation, and found free from albumin and casts, the quantity was found to be diminished, the specific gravity high, the color very dark, the reaction strongly acid, and the microscope revealed an abundant deposit of uric acid, urates, oxalates, one or all combined. These, from a physiological standpoint, indicate a decided hepatic disturbance, either functional or organic in nature. In all the cases examined post-mortem there were found marked organic changes in the liver as well as in the kidneys.

From these positive clinical and pathological facts the following deductions have been established:

First. That with a scanty flow of urine, which is high colored, of a high specific gravity, strongly acid in reaction, and loaded with uric acid, urates or oxalates, one or more combined, even with the absence of albumin and casts from the urine, we may reasonably expect to find, upon post-mortem examination, marked organic changes in the liver and kidneys.

Second. That these cases bear prolonged etherization and surgical operations badly; that they are the cases most likely to develop acute parenchymatous metamorphosis of the kidneys; and that they frequently die from retained excrementitious products rather than from so-called septicæmia.

Third. That a superficial test for albumin and casts is not a sufficient guide to the advisability of operation and to the prognosis in every surgical procedure. But for accuracy a careful study must be made, as regards quantity, specific gravity, acidity and the microscopic crystalline deposits, otherwise, the hepatic lesions may be overlooked. These conclusions are the results of a careful study of a large number of this class of cases in which necropsies were made.

MEDICAL PROGRESS.

Pulsating Tumors of the Spleen.—Arterial changes sometimes assume a prominent *rôle* in cases of aortic insufficiency. To these abnormal manifestations in the vascular system belongs also the so-called pulsating tumor of the spleen, which occurs under peculiar conditions, and perhaps oftener than has hitherto been known. Gerhardt called attention to the manifestation six years ago, and Prior last year discussed the subject. This exhausts the

literature. Prior showed that Tulpius, already in 1652, had described the condition as *lien verberens;* since which there has been no other description of the phenomenon. DRASCHE (*Wiener medizin. Blätter*, 1888, No. 1) has carefully studied a case of pulsating tumor of the spleen, so that six cases are now recorded. Five (Gerhardt, Prior, Drasche) occurred in patients with aortic insufficiency, and one (Prior) in an individual with hypertrophy of the left ventricle, without valvular lesion. In all six at the time of the manifestation there was fever from concurrent typhus, intermittent, pneumonia and pericarditis. The abnormal blood pressure, in consequence of the hypertrophy of the left ventricle, and the febrile relaxation of the vessel walls, which together give rise to increased size of the spleen, are the two conditions which afford an explanation of the occurrence of such pulsating tumors. The more frequent occurrence of such tumors with aortic insufficiency is explained by the constantly accompanying and usually marked hypertrophy of the left ventricle; that it is immaterial whether the hypertrophy of the left ventricle is due to aortic insufficiency or is a result of a demand for increased work on the part of the heart is self-evident; it is only requisite (Prior) that the hypertrophied ventricle, notwithstanding the fever, act powerfully and energetically. Drasche's work confirms and strengthens the existing views on the subject.—*Centralbl. für klin. Medizin*, June 30, 1888.

Atropine in Poisoning by Pilocarpine.—At a meeting of the Medical Section of the Association of Polish Naturalists, DR. BOLESLAW WICHERKIEWICZ (*Wiadomosi Lekarskie*, No 7, 1888) related the case of a woman, aged forty, in whom the hypodermatic injection of a sixth of a grain of pilocarpine was followed by profuse salivation and perspiration, by persistent nausea and vomiting, by incontinence of urine and feces, by extreme pallor of face, cyanosis of the lips, immobile contraction of the pupils and great acceleration of the pulse. Subsequently, there supervened frequent prolonged arrests of the pulse and spasms of the posterior cervical muscle, accompanied with rolling of the eyeballs upward and loss of consciousness. The administration of morphine, strong infusion of black coffee, alcohol and amyl nitrite failed to relieve the symptoms. The patient's condition growing more and more alarming, ten hours after the pilocarpine injection, one-fiftieth of a grain of atropine was injected hypodermatically. A striking general improvement took place almost immediately. In fifteen minutes her pulse became quite regular (eighty per minute), the pupils dilated, the respiration normal, sickness and spasms disappeared tracelessly. Two hours later the lady was found to be "quite free from symptoms and smiling."—*Provincial Med. Journ.*, July 2, 1888.

The Treatment of the Morphine Habit.—Most of the disturbances following the withdrawal of morphine appear to be due to inanition from impaired digestive activity, anorexia, vomiting, profuse diarrhœa and obstinate insomnia. If the digestive disorders are prevented or lessened, the danger of the withdrawal of the drug is removed. From personal observation, KACZOROWSKI (*Medycyna*, 1887, Nos. 28 and 29) recommends the following: After the sudden withdrawal of morphine, opium is to be administered: Tinct. opii, 20 parts; tinct. iodi, 2 parts; twenty drops to be taken every two hours, day and night. The opiate partially takes the place of the withdrawn morphine, and the iodine, as an antiferment, maintains the appetite and makes possible normal and efficient digestion; vomiting and diarrhœa are rare; the symptoms of deprivation are mild and harmless. The dose is gradually reduced to nothing, and the cure is soon complete. Confinement is not necessary, as the compulsory cure thus forcibly effected is not permanent. Constant observation is indispensable, but the psychical influence is not less important. Well-conducted hospitals are best adapted to carry out the treatment, especially in the hands of a patient and reliable female nurse. To prevent the diffusion of the morphine habit, it is necessary that physicians personally make any necessary hypodermatic injections, and that they abstain therefrom in their own persons.—*Centralbl. für klin. Medizin*, June 30, 1888.

The Treatment of Fissured Fractures of the Os Calcis.—GUSSENBAUER, before the Verein Deutcher Ærzte of Prague, stated that though fractures of the calcaneum from direct force, as from falls upon the heel or from heavy weights, are uncommon, fissured fractures are so rare that but few cases of the kind are recorded. They are especially interesting to the surgeon from the difficulty of a safe method of treatment.

In a recent case, the speaker adopted a new procedure, which, for simplicity and safety, deserves preference over other methods. A robust man, aged forty-nine, on January 12th, fell into an excavation three feet deep, throwing the right foot forward and landing on the point of the foot, and fractured the os calcis. As the attending physician could not effect replacement, the patient, on January 13th, came to the clinic. There was marked swelling in the region of the right astragalo-calcanean joint and of the lower third of the leg; strong plantar flexion was impossible; dorsal flexion painful; the tuberosity of the os calcis was raised two inches by the tendo Achillis, which separation was increased to three inches and a half on dorsal flexion. Reduction was attempted under chloroform anæsthesia. By maximum plantar flexion at the tibio-tarsal joint and flexion at the knee-joint, the dislocated tuberosity could be brought in partial apposition with the anterior fragment, but complete reduction was not possible. A retaining bandage was applied. Bony union was not looked for. Coaptation of the fragments would have been possible with Achillotenotomy, but the retention of the tuberosity in position could only have been accomplished with protracted immobilization of knee- and ankle-joints. Hereupon, Gussenbauer suggested the following expedient: The broken fragment of bone was drawn down by a Langenbeck bone hook fastened into the os calcis, by which means the fragments were accurately approximated. Then a triangular nail was drawn through the skin into the calcaneum, and such firm union of the fragments effected that the patient could make varied movements of the ankle-joint without the slightest displacement. An iodoform dressing was applied over the site of entrance of

the nail, and the foot placed upon a Petit splint. In fourteen days, the patient could move the foot without pain; in six weeks, there was complete consolidation of the fragments, and the nail was removed. The patient was discharged February 26th, without the slightest interference with function. He has since resumed his occupation of restaurateur.—*Wiener medizin. Presse*, July 1, 1888.

Antiseptic Ointments for Vaginal Touch or for Dressing Excoriations, Fissures, etc.—Demelin, in *Revue Générale et de Thérapeutique*, June 28, 1888, recommends the following:

℞—Vaseline	30 parts.
Boric acid finely pulverized	4 "
℞—Vaseline	120 parts.
Biniodide of mercury	1 part.
℞—Vaseline	30 parts.
Finely powdered iodoform or iodol or salol	4 "
℞—Vaseline	30 parts.
Creasote	1 part.
℞—Olive oil	100 parts.
Crystallized carbolic acid	10 "

The carbolized oil is advantageously employed in lymphangitis of the breast.

The Surgery of the Biliary Passages.—Courvoisier (*Korresp. Bl. für Schweizen Ärzte*, 1888, No. 3) formulates the following indications:

In case of hydrops or empyema of the gall-bladder, in consequence of occlusion of the cystic duct by a calculus, lithotripsy through the duct wall should first be attempted; this failing, cholecystotomy, with suture and depression of the gall-bladder, should be performed. If the cystic obstruction cannot be overcome, an artificial gall-bladder abdominal fistula is indicated; cholecystectomy might even be considered.

In case of complete and persistent occlusion of the choledoch duct with the consequences of biliary retention, when the obstructing agent is a stone, lithotripsy is to be attempted. If this fail, or if the obstruction depend upon cicatricial growth, an artificial gall-bladder intestinal fistula should be made.

Acute ulcerative perforation of the biliary passages by a calculus demands a laparotomy and search for the perforation. If the perforation is found in the cystic duct, ligature of the peripheral portion and extirpation of the gall-bladder are to be done; if in the choledoch duct, a ligature should be placed on either side of the perforation, and an artificial gall-bladder intestinal fistula made. A similar procedure is indicated in rupture of the biliary passages. Derangement of the biliary excretion by new growths calls for cholecysto-enterostomy.—*Centralblatt für Chirurgie*, June 30, 1888.

Injections of Ether in Cardiac Insufficiency.—Bamberger (*Wiener kl. Woch.*, No. 12) relates that in a case of fatty degeneration of the heart the hypodermatic injection of several syringefuls of ether overcame the extreme dyspnœa and the œdema, and caused a profuse secretion of urine. The writer believes that in this case the ether acted directly upon the renal secretory apparatus.—*Münchener medicin. Wochenschr.*, July 3, 1888.

The Etiology of Yellow Fever.—Dr. Paul Gibier, who was deputed by the French Government to investigate the whole question of yellow fever, has just delivered a lecture before the Academy of Sciences in Havana, embodying the results at which he has at present arrived. Before leaving Paris, he felt so convinced of the truth of Dr. Freire's views that he got himself inoculated with some of the cultures which that distinguished Brazilian physician had brought. The first insertion—made with a lancet with great care—was followed by no result whatever. A week later some of the attenuated virus was injected subcutaneously, and this produced such violent effects that Dr. Gibier declares nothing in the world would induce him to submit to a repetition of it

Since his arrival in Cuba, he has made post-mortem examinations of a number of persons who have died of yellow fever, some of the examinations taking place only two hours after death, and one of them within fifteen minutes from the moment life became extinct. The examination of the blood taken from the heart in these cases, as well as the inspection of the urine, the bile, the pericardial fluid, the liver, the spleen and the mesenteric glands convinced him that none of these organs contains any microbes. He, however, discovered in the black matter always found in the intestines a bacillus presenting many points of resemblance to the so-called comma-bacillus of cholera, being sometimes curved and occurring in some cultures in a spiral form, possessing also the property of liquefying gelatin. This bacillus, when cultivated in peptonized broth, blackened the sides of the tubes; and when a few drops of the culture were injected into the intestine of guinea-pigs it sometimes proved fatal, the intestinal contents then showing a great resemblance to those found in yellow fever patients. In dogs, the injection of a few drops into the small intestine rapidly produced violent effects—vomiting, diarrhœa and, the night following, pyrexia. Cultures of this bacillus had a smell resembling that of the black vomit. A moist heat of 140° F. destroyed the bacillus in a few minutes; desiccation also proved fatal to it in less than twenty-four hours.

This last observation led Dr. Gibier to suggest that if this bacillus was really the cause of yellow fever, the immunity of inland districts might thus be explained, the comparative dryness of the air destroying the virus. It developed extremely well in sea water charged with organic matter; living, too, for a long time side by side with the ordinary microbes of putrefaction, so long at least as the medium did not become acid, for even a very slight degree of acidity destroyed the organism in a few hours.

In confirmation of observations made in the laboratory, Dr. Gibier mentions that he has several times had an opportunity of demonstrating the same circumstance in the dead-house, the contents of the intestines, when they have become acid some hours after death, ceasing to show the presence of the bacillus.

Since writing on this subject previously, Dr. Gibier has had opportunities of examining the bodies of foreign sailors who have died in the civil hospitals of Havana, and he has been able to demonstrate the presence of the bacillus in those who had suffered from yellow fever and its absence in those who had died from other diseases.

His opinion is that yellow fever is due to the development of the microbe in the intestine, the affection being, therefore, essentially a local one.

As to treatment, in addition to tonics and stimulants when required and frictions for the renal complication, he advises that the main treatment should be directed to the intestine. Every morning a good purge should be given—the first day 1 to 1½ ounces of sulphate of soda; the second day, 1½ ounces of castor oil, and the third day 15 grains of calomel, the same series being repeated during the rest of the first week. If the medical man is only consulted on the fourth, fifth or sixth day, the stomach should be washed out previously to the administration of purgatives, the colon being subsequently irrigated with a special tube, in order to get away as large a quantity of the toxic matter as possible. A case is mentioned which was apparently hopeless, the patient being semi-comatose, in which an enema produced an extremely copious stool, followed by rapid improvement and ultimate recovery. In fact, Dr. Gibier would treat yellow fever as he would an infecting ulcer, "by washing and disinfection." He recommends in addition to hydrochloric acid lemonade, which is taken as a drink, three different mixtures, all to be taken together. 1. Perchloride of mercury, $\frac{5}{7}$ to 1 grain; brandy, 2 ounces; mucilage, 2 ounces; infusion of coffee, 5 ounces; the whole to be taken in numerous divided doses during the twenty-four hours. 2. Naphthalin, 7½ grains, made up into a paste; from five to ten times this quantity to be taken in the twenty-four hours. 3. Tannic acid, 7½ grains, made into a paste; to be taken from six to ten times in the twenty-four hours. A case is given in detail, in which this treatment immediately changed the aspect of an apparently very grave case, the patient making a good recovery.—*Lancet*, July 14, 1888.

Excision of a Large Portion of the Os Ilium.—GUSSENBAUER, before the Verein Deutscher Ærtze, in Prague, exhibited a woman, aged forty-six, in whose case a large portion of the right ilium had been removed on account of an enchondroma. Following an injury in the right iliac region, a swelling formed, which grew rapidly, was painful and impeded locomotion. When the patient was first seen, on February 20th, a nodular tumor of the size of an adult's head and of the consistency of cartilage was detected in the right half of the pelvis, occupying the right os ilium, and extending from the sacro-iliac synchondrosis deeply into the iliac fossa. On February 23d, the extirpation of the tumor and of the involved portion of the os ilium was performed. The large cavity made was drained. The wound healed kindly. The bandage produced compression of the ascending colon, in consequence of which, tenderness, hiccough and constipation arose, disappearing, however, after removing the cause.—*Wiener medizin. Presse*, July 1, 1888.

The Cardiac Insufficiency of Fatty Heart.—HÖGERSTEDT (*Petersburg med. Wochenschr.*, Nos. 47 and 48, 1887) states that in this there are two distinct therapeutical indications: 1. The treatment of the acute manifestations of cardiac failure; 2. To overcome the chronic insufficiency.

To meet the first of these, he advises the use of ether and alcohol. With the onset of the asthmatic paroxysm, he recommends an ice bag to the cardiac region, peripheral irritation by means of friction and hot applications to the extremities, a glass of wine and the subcutaneous injection of ether or whiskey. Should these measures fail, and danger of cardiac paralysis arise, then only should resort be had to digitalis. The author warns against the use of morphine and, especially, of opiates. Their usefulness is slight, and they may do harm by increasing the feebleness of the heart.

For the chronic insufficiency of the heart, the author recommends an absolute milk-diet. Such a diet is unfavorable to the formation of fat. It supplies the organism with sufficient for its needs, but with a deficiency of carbohydrates and fat. With a continued milk-diet the signs of chronic insufficiency, as far as possible, are made to disappear, and the force of the heart is increased. It is probable that the reduction of fat which affects the body also includes the heart.

In his case the author used with good results one drop of a one per cent. solution of nitroglycerin.—*Centralbl. für die gesammte Therap.*, July, 1888.

Sulphonal.—LEHMANN (*München. medizin. Wochenschr.*, July 10, 1888) relates the case of a patient with asthma and insomnia, in which, chloral and morphine failing, fifteen grains of sulphonal given at bedtime proved an excellent and agreeable hypnotic.

MARTIN (*Med. Neuigkeiten*, No. 29) recommends sulphonal for the night sweats of phthisis. Doses of seven and a half grains at bedtime prove serviceable and afford the patient a quiet and natural sleep of four to six hours.—*München. med. Woch.*, July 10, 1888.

Cold Air Inhalations in Phthisis.—As the bacillus tuberculosis is only developed at a temperature above 37.5°, WORMS, of Riga (*Petersb. med. Woch.*, No. 25), recommends inhalations of cold air in phthisis. The patient, protected from the wind, should deeply inhale the external air through the mouth during the greater part of the day; during the night, the room is to afford limited access of cold air. Loss of heat by the skin is to be prevented by warm clothing. At the same time abundant albuminous and oleaginous nutriment and some alcohol are to be given; physical exercise and pulmonary gymnastics are to be recommended. Unfortunately, there are no statistics to support the author's theory.—*Munchen. medizin. Wochenschr.*, July 18, 1888.

Staining of Bacilli in Tuberculosis.—Tubercle bacilli are readiest and best stained by Gabbett's method, as described by GÜNTHER in the *Wiener klin. Woch.*, No. 13.

I. The dry preparation is placed for two minutes in a solution of fifteen grains of fuchsin in three and a quarter ounces of a 5 per cent. solution of carbolic acid and two drachms and a half of absolute alcohol.

II. The preparation is then placed for one minute in a solution of thirty grains of methyl-blue in three and a quarter ounces of sulphuric acid. The preparation is next rinsed in water and examined in this medium; or, better, is treated with absolute alcohol and examined in Canada balsam. The bacilli are red, the field blue.—*München. medizin. Wochenschr.*, July 10, 1888.

For Metrorrhagia.—According to BAMBELON (*Pharmac. Centralhall*, No. 9), a decoction of one to two teaspoonfuls of Capsella Bursa Pastoris or Shepherd's purse is equally as efficient in metrorrhagia as ergotin.—*Deutsche medizin. Wochenschr.*, July 12, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

Philadelphia.

SATURDAY, AUGUST 4, 1888.

PERNICIOUS ANÆMIA.

That pernicious anæmia is one of the most obscure diseases is due not only to the short time it has been studied but, to a greater degree, to the variety of its symptoms. From the diversity of these in different cases, it is difficult to recognize the type, and until this is done, the question as to whether pernicious anæmia is really an independent disease or not must remain an open one. At present the mass of testimony, or, at least, of opinion, tends to the belief that it is an independent disease, but with a varying etiology; and as the latter factor is studied the disease can be divided into cases with and cases without a known cause. In time this will probably tend to lessen the number of cases described as essential anæmias.

Before that, much study must be devoted to single symptoms and defining their relation to the disease. The difficulty of such a study is illustrated by a recent paper by Trechsel, on the "Etiology of Progressive Pernicious Anæmia" (*Rev. med. de la Suisse Romande*, No. 6, 1888), which contains a very good account of the disease and the discussion of a case under the author's observation, which he considers as presenting symptoms of locomotor ataxy. The case was that of a young woman who became anæmic during pregnancy, was delivered normally and without much hemorrhage, but never recovered strength; her appetite was lost, vomiting occurred frequently and the patient so lost strength that she could not walk. The knee-jerk was diminished, as was the muscular sense and also, though to a less degree, the cutaneous sensibility. Toward the end, lightning pains came on. There was no autopsy.

In citing this case as one of tabes, Trechsel says that Lichtheim has reported two similar cases, in which degeneration of the posterior columns of the spinal cord was found, and he states his belief that there was a fatty degeneration of these columns similar to that found in other organs in pernicious anæmia. He admits, however, that Lichtheim did not pronounce upon that point; and it seems to us a mistake on his part that he did not follow that acute clinician's example; for there is evidently little ground, from the clinical history as detailed, to warrant the diagnosis of tabes. The knee-jerk was diminished, but not absent, and we learn nothing about the pupils, ataxia or Romberg's symptom. The hæmoglobinometer estimation is useless as bearing on the diagnosis of pernicious anæmia, a fact of which the writer appears to be ignorant, if we may judge from his remarks on the diagnosis. He says that the hæmoglobin "seems to be in proportion to the red corpuscles," a statement inconsistent with the facts, as the relative increase of hæmoglobin above the proportion of the corpuscles is one of the most marked characteristics of this form of anæmia. Thus it seems doubtful that Trechsel's case was really one of pernicious anæmia; so that our knowledge of the disease is no greater than before.

To return to tabes, even more marked cases than this have been reported, in which no lesion at all in the cord could be made out *post-mortem*. It is difficult to understand, too, how or why the cause of the fatty degeneration of the other organs, presumably anæmia, could produce such systemic degeneration as that characteristic of tabes.

LEAD ENCEPHALOPATHY.

The cerebral disturbances due to lead poisoning are among the rarest of all nervous diseases. Partly owing to the scant opportunities offered for making *post-mortem* examinations in such cases, but little is known of the anatomical changes underlying the morbid conditions. Lead is found in the nervous as in many other tissues; Kussmaul and Maier have described periarteritis in the cerebral cortex, and sclerosis of the sympathetic ganglia; the latter fact was already known to Tanquerel in 1842. In cases in which death has ensued during eclamptic seizures,

aside from hemorrhage in the pons in one case of Lemaire. nothing more was noted than anæmia and œdema. which, of course, are not peculiar to the disease. That the anatomical changes are not simple may be concluded from the variety of forms presented clinically. Our readers will no doubt recall the interesting paper by Dr. Stewart. in THE MEDICAL NEWS of last year, in which many of the cases presented eclamptic phenomena; and this is the commonest form of plumbic encephalopathy.

WICKHAM (*L'Union Médicale*, No. 80, 1888) has reported a case in which progressive paralysis was apparently initiated by lead poisoning. The patient was an artist in water-colors, thirty years of age. There was no syphilitic or alcoholic history, but he belonged to a neurotic family. His disease began in the spring of 1887, with disturbed intellection, irritability and trembling of the fingers. This increased so that at the end of the year he had to give up work. He was seen then by Dr. Wickham, cachectic and with the symptoms noted. and with a blue line on the gums. It appeared that he used white lead in his work, wetting the brush in his mouth and rubbing off the color with his fingers.

Gastro-intestinal symptoms soon followed, and later albuminuria. His mental condition became worse. Loss of memory was marked; he would spend hours arranging furniture in the dwelling; believed that he was about to invent a process for engraving that would make him wealthy; he had periods of "reasoning mania." His speech became stammering. At no time, however, was there lingual ataxia, trembling of the lips or pupillary disturbance. Incontinence of urine or feces and alteration of knee-jerk were also absent. He was studied by Charcot, who was struck by the difference between the man's general appearance and his writing. The latter was so perfectly characteristic of general paralysis that he made a diagnosis to that effect, with intercurrent lead poisoning. The treatment consisted in the use of sulphur baths, iodide of potassium and morphia. There was but little change until February, when improvement of the gastro-intestinal symptoms began, soon followed by improvement of the mental and nervous symptoms. In April the patient was declared well. He could write as in health, and both mind and body seemed perfectly normal.

If, as Wickham remarks, the diagnosis of Charcot be accepted, the patient must now be in a period of remission, but in such remissions there is rarely complete absence of psychical as well as physical symptoms, even for so short a time as that elapsing before the case was reported. If the diagnosis of general paralysis is rejected, it is difficult to doubt the existence of a saturnine pseudo-paralysis, a disease curable by eliminating the toxic substances. It is possible, also, that the case is one of lead poisoning in a neurotic, in which cerebral symptoms and tremor preceded colic, and in which acute mania supervened.

Whichever of these the case proves to be, it shows forcibly the difficulty of diagnosticating progressive paralysis, and more forciby still the necessity for a guarded prognosis, even when the diagnosis seems assured.

THE PREVENTION OF FOOD ADULTERATION.

THE administration of the laws of New Jersey to regulate the sale of oleomargarine and other imitations of dairy products and to prevent the adulteration of food and drugs has recently been entrusted to DR. WM. K. NEWTON, Dairy Commissioner of the State, in order to impart to it increased efficiency, and the result has justified the expectation. The report of the Commissioner for 1887 furnishes evidence of intelligent and energetic work, in detecting adulterations in articles of food, and in punishing the offenders. The enforcement of the law regulating the sale of oleomargarine and other imitations of dairy products has well nigh driven these articles out of the market. The act to prevent the adulteration and to regulate the sale of milk, passed several years ago, has been made operative in nearly all the cities and towns of the State, with the result of greatly improving the quality of this important article of food. The law relating to the adulteration of food and drugs, which up to the present time had been a dead letter, has been revived, and a large amount of labor has been expended in analyzing the more common articles. When these articles have been found adulterated, the dealers have been warned of the fact and served with a notice that a repetition of the offence would be followed by prosecution. New Jersey has thus placed herself in line with Massachusetts, New York and some other States. in making open and active warfare against the deceptive and fraudulent and, frequently, hurtful practice of adulteration.

These organized efforts at the suppression of an infamous practice are, as yet, in their infancy, but they have already accomplished excellent results, a

large part being due to the moral effect of organization under efficient laws. Other States will eventually establish a service of food inspection and analysis, when its necessity is better understood and its advantages are more thoroughly appreciated.

The adulteration of food may be harmless, in which case an imposition is practised upon the purchaser, who pays for what he does not want, besides obtaining an article deficient in nutritive value; but a more serious aspect of the subject is that in which hurtful or poisonous materials are added to food, as in the recent cases of poisoning from the admixture of chrome yellow in certain products of the bakehouse, which fact was accidentally discovered after fatal consequences had attended the use of the toxic agent. It is true that the law punishes the offender when serious effects are traced to his acts, but the aim of the law should be protective and preventive, as well as remedial, and by the authorization of well-known agencies it should discover and punish the offence of tampering with the food supplies of the people. The protection and preservation of the health and lives of the people belong to the highest duties of government, and unless this truth is realized by our legislators, and they use their opportunities for thus promoting the public good, they become, in a measure, morally responsible for the evils resulting from a tacit license to trade in fraudulent and injurious preparations of the commodities of life, and thus show themselves as grossly incapable of discharging the important duties entrusted to their care.

Dr. Koller, the discoverer of the anæsthetic properties of cocaine, has removed from Vienna to New York City.

Prof. Leidesdorf, Professor Extraordinary of Psychiatry at the University of Vienna, has resigned in consequence of ill health. He has been a teacher at the University of Vienna since 1857 and chief of the Insane Clinic since 1875.

A new kind of enterprise has been developed in New York City, in connection with the starting of a new evening newspaper, by the engagement of a physician residing in one of the poorer quarters of the city to treat sick children whose parents are unable to employ medical attendance. He is engaged for the summer months, when the mortality among infants is especially high, to visit the sick at their homes and also to write articles for the newspaper on the preservation of the health of children.

SOCIETY PROCEEDINGS.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-fourth Annual Meeting, held at New London, Conn., July 18 and 19, 1888.

Wednesday, July 18th.—Evening Session.

(Concluded from page 111)

Dr. William Oliver Moore, of New York, read a paper on

HYSTERICAL BLINDNESS IN THE MALE, WITH A REPORT OF THREE CASES.

Case I.—Male, æt. twenty-five, farmer. Family history good. During past two years, had suffered with nervous symptoms. Did not smoke or drink. In June, 1886, complained of failing vision in left eye. When seen, June 16, according to patient's statement, vision in left eye = 0; right eye normal. Ophthalmoscope showed fundus normal, except a slight notch of opaque nerve fibre near the papilla. Testing with prism and candle gave double vision, as did pressure on one eyeball. The patient was informed that treatment by electricity would cure him in a few days. A strong faradic current was applied, causing the patient to jump from his chair, exclaiming that there already was improvement. In ten days $V. = \frac{20}{XX}$. Emmetropic.

Case II.—Male, æt. twenty-two, student and farmer. Fine looking. History of insanity in the family. Eighteen months before coming under observation, atropia had been instilled by a physician to determine whether or not glasses were required. He thought from the effect of the atropine that he was going blind. He then put on smoked glasses, subsequently bandages and kept in a dark room. He would not open the lids and declared that he was blind. For ten months he kept in a dark room, with covering over the eyes. On examination, the lids were closed, but not by spasm; the cornea clear. V. = O. Ophthalmoscopic examination under ether, normal fundus. Hysterical blindness was diagnosticated and a favorable prognosis given. Canthoplasty was then performed. Recovering from the effects of the ether the patient opened his eyes and evidently saw clearly. He was told that the cause of the disease had been discovered and that he would be well in a few days. In two days he was walking around without glasses. Has remained well since.

Case III.—Boy, æt. eighteen. Developed blindness in right eye after a disappointment at school. Normal appearance of eyes. Tests with prisms and colored glasses showed that vision was present. Ether was administered and patient assured that he would be well, and under electricity recovery was rapid.

Dr. Charles A. Oliver, of Philadelphia, presented a

DESCRIPTION OF A SERIES OF TESTS FOR THE DETECTION AND DETERMINATION OF SUBNORMAL COLOR-PERCEPTION (COLOR-BLINDNESS) DESIGNED FOR USE IN RAILWAY SERVICE.

It is a well-known fact, both from theoretical and practical standpoints, that many "color-blinds," especially

those of medium grades, have the power, even by daylight, of differentiating slight variations of shade when placed at the ordinary distance (forty inches) for wool selection employed in the detection and determination of "color-blindness." The writer has been induced, in the hope of overcoming the dangers that might arise from this power, in such important departments as railway, marine and naval service, in which the safety of lives and the protection of property are oft-times solely dependent upon proper recognition of color at great distances, and frequently through the intervention of more or less translucent media, to combine two modifications of his method of color selection with a simplified plan of the former procedure, by which the candidate is placed in the actual position of after-work, and under exactly similar circumstances as during employment. The method is divided into three parts:

First. The selection and registry of a definite number of loose wools from twenty-three pure and confusion match skeins thrown upon a dead black surface at a distance of forty inches.

Second. The selection and registry of the same number of similar reflected colors under various intensities of diffuse daylight stimulus, placed at distances requisite for safety.

Third. The selection and registry of transmitted colors under various intensities of artificial light stimulus placed at distances requisite for safety.

In addition to the advantages shown to refer to this first test alone, the method has the following additional ones: 1. Much faster in time than any other method. 2. The selection of loose wools at a distance. 3. No necessity for an expert except in doubtful cases. 4. Employment of the same character of signals for testing as is used in daily routine. 5. Placing the eye during testing at a distance necessary for future safety. 6. Bringing the eye during testing directly before the true condition of weather experienced whilst it is upon duty. 7. Test and match colors all graduated in proportionate sizes.

Dr. Oliver also reported a

CASE OF EMBOLISM OF THE CENTRAL RETINAL ARTERY.

The patient, a young man, was seen October 5, 1887. Twenty-six hours previously, while slowly walking in the shade, he was suddenly seized with blindness in the left eye. There were no other symptoms, and there had been no previous illness. The right eye was normal. Ophthalmoscopic examination of left eye showed clear media, nerve substance of a gray tint and swelling of the retina. All the retinal vessels were reduced in size. The veins were somewhat contracted, especially toward the nerve entrance. The characteristic cherry spot in the macular region was distinct. There was a small hemorrhage on the disk. Careful physical examination failed to reveal any lesion in other parts of the body. The case was kept under observation for some time, but there was no return of vision, the patient remaining completely blind in the left eye.

Dr. H. D. Noyes remarked that the result of autopsies shows that the great majority of these cases are really due to thrombosis and not to embolism.

Adjourned until Thursday morning.

Thursday, July 19th.—Morning Session.

Dr. Samuel Theobald reported

A CASE OF DOUBLE CONGENITAL IRIDEREMIA

in a child whose mother exhibited a congenital coloboma of each iris.

James O., aged eighteen months, was seen December 9, 1887. His mother brought him on account of the red appearance which the pupils presented. Upon examination, besides a congenital squint of the left eye, complete absence of each iris was discovered. The lenses were clear and there seemed to be, at least in the right eye, fairly good vision. The interest of the case lies in the fact, accidentally discovered, that there existed in the mother a congenital coloboma of each iris. In her right eye the coloboma was large, its direction being directly upward; in the left eye it was somewhat smaller, and was in an upward and outward direction. In neither eye was the choroid involved in the congenital defect. The mother volunteered the statement that an older child had had a similar appearance of the eyes, so that it is probable that to this mother with congenital coloboma there was born not only one but two children with absence of the irides.

Dr. David Webster, of New York, thought that the direction of the coloboma in the mother's eye was unusual. He did not recall an instance in which the coloboma was upward. It is almost always downward.

Dr. Randall, having had occasion to look up the literature of this subject, said that there were a number of cases reported of coloboma inward or outward but not upward.

Dr. T. Y. Sutphen, of Newark, N. J., read a paper on

PUNCTURE OF THE RETINA FOR DETACHMENT.

The results of three operations were reported. A male, sixty-two years of age, sought treatment April 1, 1887, for a cloudy appearance before the right eye. This he had noticed only a few days. He was near-sighted, but had never used glasses. Examination, R. S. $= \frac{15}{C}$ raised to $\frac{15}{XX}$ by $-\frac{1}{16}+$; field of vision defective downward and toward the median line. Tension slightly diminished. L. S. $+\frac{15}{C}$, raised to $\frac{15}{XV}+$ by $-\frac{1}{16}$. Ophthalmoscope showed myopia with choroiditis in both eyes. In the right eye the retina was found detached in its upper and temporal portion. The patient refused to undergo vigorous treatment in bed. He was given iodide of potassium in gradually increasing doses, rest being enjoined.

Five months later the patient returned with commencing detachment in the upper and temporal portion of the left retina. He was then kept in bed for two weeks, with the eyes bandaged, while profuse diaphoresis was frequently induced, but without benefit. He was then sent to the country, the iodide being continued. By December 1st there was in the right eye only perception of light; in the left there was vision confined to the outer and lower field. On this date puncture of the retina from beneath the detachment was made. Thorough antisepsis was employed; cocaine was instilled, a sickle-shaped needle was thrust into the globe between the

insertion of the external and inferior recti muscles, on the equator and on a plane with the lens; it was pushed onward until it was thought that the retina had been pierced. It was then withdrawn with a sweeping motion, the object being to enlarge the opening in the retina. Atropine was instilled, the eyes bandaged and the patient ordered to keep quiet. The following day, the subretinal fluid had disappeared, field of vision was normal, a red reflex was obtained from the fundus in every direction and the patient could distinguish large objects. Bandage was reapplied. Two days later, patient could count fingers at twelve feet, the retina appeared in the normal position, but the vitreous was quite cloudy. The vision continued steadily to improve. December 10th, a similar operation was performed on the left eye. Two days later there was marked enlargement of the field of vision, but some detachment was still to be seen on the temporal side. December 16th, field of vision in both eyes normal. No detachment of retina in either. The patient remained in bed twenty-eight days. February 10th, detachment began to reappear in the left eye and by March 3d it was as great as before. Needling was again performed with the escape of very little subretinal fluid. March 5th, field again normal. April 1st, partial return of detachment in left eye. July 6th, seven months after first operation, S. R. $= \frac{15}{C}$, raised to $\frac{15}{XL}$ by $-\frac{1}{20}$, no return of detachment, field of vision normal, blindness for red. In the left eye, almost complete detachment of the retina

After referring to the history of the operation, the speaker said that the interesting facts were these: The apparently perfect safety of the operation under modern antisepsis; one success and two failures under exactly similar conditions, barring the escape of the fluid outward in the successful case; encouragement to try this operation in otherwise incurable cases; the absolute freedom from all reaction. The best results will probably follow when the operation follows closely upon the subsidence of the acute affection causing the detachment. The chances of success are increased by a free flow of fluid outward. It was suggested that a narrow Gräfe knife might be used after accurately measuring the depth of the detachment, provided the point be so directed that the wound in the retina shall be directly opposite the lateral puncture.

Dr. J. F. Noyes, of Detroit, had tried operative procedure in only one case. He drew off the fluid with a hypodermatic syringe. After drawing off the fluid the retina returned to its normal position, and the outline of a small tumor was discovered. The detachment soon returned; the ball was enucleated one year later.

Dr F. P. Capron, of Providence, reported

A CASE OF GLIOMA.

The patient was a child three and a half years of age. The growth was removed, but has since involved the submaxillary glands and the glands in the neighborhood of the ear. Photographs showing the appearances were presented.

Dr. D. B. St. John, of Hartford, asked whether aid in the diagnosis between glioma and other affections was afforded by attention to the state of the tension.

Dr. David Webster, of New York, had never been able to detect any increase of tension until the second or inflammatory stage had been reached. There is always increase of tension. In at least two cases he had diagnosticated glioma from the history, with the existence of increased tension, when no tumor could be discovered. There is now on record a case in which Dr. C. R. Agnew removed both eyes of a child, one year of age, for glioma. This was fifteen years ago and the individual is still living. In this case the diagnosis was verified by microscopical examination. In some cases in which the diagnosis was made, but enucleation refused, the patients are still alive and the disease has not progressed, retrograde metamorphosis having, it is said, taken place.

Dr. W. F. Norris believed that in true glioma retrogressive metamorphosis does not take place. Fatty degeneration may occur in parts of the growth, but he was not aware of a case in which the growth entirely disappeared. Such cases are, he thought, instances of mistaken diagnosis. The diagnosis is difficult unless the growth has reached such a size that the vessels may be seen in it.

Dr. Swan M. Burnett presented some

MODELS EXHIBITING REFRACTION BY CYLINDERS.

It was shown how the refraction and the facial line change with the variation in the strength of the lens and with the alteration of the angle of crossing of their axes. The models were made, at his suggestion, by Mr. C. F. Prentice, of New York. Diagrams were exhibited showing, by geometrical construction, how it was possible to tell the course of any given ray after its refraction by any two cylinders of differing power and at any angle of crossing of their axes. A formula applicable to any axis of crossed cylinders, calculated by Mr. Prentice, was also shown.

Dr. Edward Jackson then read a paper on

DESIGNATION OF PRISMS BY THEIR REFRACTIVE POWER.

The author pointed out the inconveniences and errors arising under the present method of designating the strength of prisms, and recommended their designation by their refractive power as much more accurate.

A committee consisting of Dr. H. D. Noyes, Dr. Edward Jackson and Dr. Swan M. Burnett was appointed to take the matter into consideration, and report at the next meeting.

Dr. David Webster then read a paper on

EXTRACTION OF A PARTIALLY ABSORBED CALCAREOUS LENS.

March 15, 1888, C. C., æt. twenty-three, consulted Dr. Agnew and the author at the Manhattan Eye and Ear Hospital. She had phthisis bulbi left, and in the right eye were the calcified remains of a mostly absorbed lens, with a discolored atrophic-looking iris attached to the membranous mass by numerous adhesions. Visual field good. V = fingers at two feet. The vision of the left eye had been lost through a blow with a whip at the age of two years. A catarrh developed in the right eye some time afterward. Seven years ago (1881), her sight having been lost four months, both eyes were several times operated on by a surgeon in another city. Violent inflammation followed one or more operations on each of the eyes. Eighteen months ago another needling was done by another surgeon, by which sight was somewhat improved. The atrophic eye of late has been painful and tender on pressure. March 16th, Dr. Agnew enucleated the atrophic eyeball. A calcified plate was found in the

choroid and a small calcareous lens. While the patient was still under ether, he performed an iridectomy on the right eye. April 27th, Dr. Webster divided, with Knapp's knife-needle, two or three of the adhesions which were on the stretch. At least one could be heard to snap when cut An attempt to penetrate the thinnest looking portion of the membranous mass failed. There was considerable effusion of blood, which was soon absorbed. May 14th, an attempt to remove the pupillary obstruction with a sharp hook failed. Very little reaction. June 6th, with a keratome bent on the flat, a wound, as for iridectomy, was made on the supero-nasal corneal border. The pupillary obstruction was drawn out and cut off close to the cornea. Not a drop of vitreous escaped. There was some pain in the eye for three or four hours, probably the reaction from cocaine. Four days later, pain again appeared and was relieved by iced cloths. June 18th, fundus normal, no floating bodies in the vitreous, but the remaining portion of the pupillary membrane, which, by the way, was very thick and so tough that the iris scissors would scarcely cut it, extended backward horizontally and flapped up and down with the movements of the eye. June 22d. $V = \frac{20}{XX}$ with $-\frac{1}{3\frac{1}{2}}$. Reads Jaeger No. 1, with $+\frac{1}{2\frac{1}{4}}$. June 26th, discharged, wearing the above lens.

DR. S. THEOBALD exhibited an

UNUSUALLY LONG CILIUM.

The hair was over an inch in length, and was removed from the eyelid of a young lady suffering with some conjunctival irritation; the other cilia were of the usual length.

OFFICERS FOR THE ENSUING YEAR

were elected as follows:

President.—Dr. Wm. F. Norris, of Philadelphia.

Vice-President.—Dr. Hasket Derby, of Boston.

Treasurer.—Dr. J. S. Prout, of Brooklyn.

Recording Secretary.—Dr. Samuel B. St. John, of Hartford.

It was decided to hold a special meeting for the consideration of scientific matters only, September 19, 1888, at the Arlington Hotel, Washington, D. C.

The regular annual meeting will be held on the third Wednesday in July at the Pequot House, New London, Connecticut. Adjourned.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, June 12, 1888.

C. B. NANCREDE, M.D., IN THE CHAIR.

DR. JOHN S. MILLER read the following paper:

A CONTRIBUTION TO THE STUDY OF BONE REPAIR.

The recent observations of Macewen[1] have done much to stimulate the study of bone repair and have not thrown a little light upon the function of the medullary cells in osteogenesis.

The resort to mechanical irritation of the medullary tissues as a means of accelerating bone repair is an old procedure. Nancrede[2] claims a priority in this for America. As far back as 1793, Eve[1] relates that the lay surgeons of the frontier were wont to make multiple perforations of the external table of the skull when necrosis followed the Indian mutilation of scalping; and twenty years ago Agnew resorted to the same procedure in a case of injury to the head. A fatal termination of the case, however, by encephalic complication, rendered the experiment incomplete. Reports of success by this procedure have been recently multiplied to an extent which will excuse us from repeating them in detail.

That furthermore, medullary proliferation is not only an element in osteogenesis, but is of itself sufficient to that end, without periosteal coöperation, is evidenced by the case of Macewen,[2] in which a considerable restoration of the humerus was secured "by bone-transplantation," after a suppurative inflammation had destroyed both the shaft and its periosteum. The date of this observation is 1878.

The patient was a boy, two years of age. A suppurative periostitis of the right humerus of nine weeks' duration had resulted in total necrosis of the entire diaphysis, and this latter had been removed, leaving a tube of granulation material lining the periosteum. This tube had been kept patent by suitable dressing, until the whole space had become filled with granulation tissue, and had finally become a mass of cicatricial tissue. No bone had grown from this periosteum, except from a small portion next the proximal epiphysis, where at the outset the periosteum had been found covered with plaques of adherent osseous tissue. In the remainder there had been no osseous deposit, the result being a flail-like arm, which the patient found so useless that the parents desired its removal.

Macewen determined, however, upon another procedure. An incision was made into the upper third of the arm, exposing the head of the bone, to which was found attached a spike-like process of cartilage. This was removed, leaving as remains of the diaphysis a portion of bone one and three-fourths inches in length. From this point a sulcus about two inches in length was made in a downward direction between the muscles. The former presence of bone was nowhere indicated, there was no vestige of periosteum, and the sole guide as to the correct position into which the graft was placed was an anatomical one. Two wedges of bone were then removed from the tibia of a patient aged six years, with anterior curves. The face of the osseous wedges consisted of the anterior portion of the tibia, along with its periosteum, the wedges gradually tapering toward the posterior portion of the tibia.

After removal they were cut into minute fragments with the chisel, quite irrespective of the periosteum. The larger number of the fragments had no periosteum adhering to them, having been taken from the interior of the bone.

They were then deposited in the muscular sulcus of the boy's arm, and the tissues drawn over them and carefully adjusted. The wound healed without pus production. Two months after, a portion of bone an inch in length and three-quarters of an inch in thickness was found firmly attached to the upper fragment of the humerus.

Two other wedges of bone, larger in size, were similarly dealt with and inserted two months subsequently to the first graft, and a third couple were placed in position five months after the first. These filled up the gap in the arm to the extent of four and one-quarter inches. The arm then measured six inches in length.

[1] Annals of Surgery, vol. vi. pp. 289 et seq., 389 et seq.

[1] Remarkable Cases of Surgery, p. 35. Philadelphia, 1857.

[2] Loc. cit., p. 301.

Soon the utility of the arm was greatly restored. Seven years afterward he was seen and examined. The shaft of the humerus was found to have increased in length by one and three-quarters inches, being then seven and three-quarters; and it had increased in circumference to a marked extent and assumed a somewhat irregular shape. The length of the sound arm had, however, considerably outstripped the length of the engrafted humerus. The boy could use the arm for many purposes—taking his food, adjusting his clothes and in many games.

Whether the introduction of proliferating medullary cells into ordinary connective tissue granulations may convert the whole into osseous tissue, or whether a few osteoblasts will, so to speak, leaven the whole mass, is a question involving grave doubt, but the affirmative would seem to receive some support from the case which Nancrede[1] relates in 1883. An extensive laceration had caused denudation and necrosis of the ulna in two-thirds of its extent. The process of repair had been delayed; the operator drilled numerous holes through the sequestrum into the medullary canal, and, to quote his own words, "in a few days granulations sprang up from the ulna and fused with the granulations of the soft parts, and, in course of time, the fragment was separated."

That the procedure in this case had the effect of stimulating osteogenesis from within we can readily believe; but concerning the fusion with granulation tissue without, a more accurate observation than is recorded by Nancrede is desired. Although by analogy we might conceive it possible, inasmuch as repair within the bone is by ossification of an embryonic tissue derived from the connective tissue around the bloodvessels of the medullary space. A similar case is reported by Macewen,[2] in which granulations appeared upon a surface of bone completely denuded of its periosteum and gradually spread until they became united with the granulation tissue at the periphery of the wound. Macewen, however, infers from this observation that "The periosteum covering a bone may be completely destroyed or permanently removed, yet the denuded bone may not only retain its vitality, but may throw out cells which will cover it and form a new periosteum."

The presence of these cells would seem to confirm Macewen's dictum that the periosteum has no part, whatever, in the regeneration of bone; but the following case demands a different hypothesis for its explanation:

D. M., aged fourteen years, suffered from an osteomyelitis of the right tibia, resulting in total necrosis of its diaphysis. A complete involucrum had formed around the sequestrum and afforded an unsteady support for the body weight. It was covered with the thickened periosteum. A number of fragments had been removed from time to time, and the parents had refused to entertain for him the proposal of amputation. The case, however, when it came into my hands, had from septic infection become so desperate that I was compelled to do something radical at once.

Exposing the shaft, or rather the involucrum, throughout its whole length, Dr. Miller made, with trephine and saw, a fenestrum large enough to permit the removal of the remaining sequestra and cleared out the whole canal. Both epiphyses were found carious upon their exposed surfaces and were scraped to the limit of safety. In a few days a superficial necrosis took place upon the inner surface of the tube.

Demarcation was, however, promptly effected by the free use of aluminium acetate—

R.—Pot. et alum. sulph. . . . 1 part.
Plumb. subacet. . . . 5 parts.
Aquæ bull. . . . 100 parts.—M.
Filtra.

and a layer of fine granulations became the field for any osteogenesis which we might hope to witness. During the long process of repair, with the carious epiphysis as a never-failing source of bacterial supply, it was no trifling task to keep this extensive opening dry and sterilized. Furthermore, frequent dressings caused great nervous prostration.

The requirements of the case were successfully met by a mixture of iodoform and starch, in proportions which varied with the changing conditions. The cavity of the wound was filled with this dry powder, and to the whole was applied a closed dressing of gutta-percha tissue. The purpose of the starch was to absorb the excess of moisture incident to a closed dressing, as well as to dilute the iodoform. As soon as the powder became saturated, it was removed by a stream of sterilized water, and the wound was filled and closed as before. The intervals of dressing were gradually increased from three to ten days. These details are given, because, without them or similar ones, we would wait in vain for the desired repair. In process of time the hollow of the involucrum became completely filled with granulation tissue, which continued to extend until it fused with the granulations from the soft parts, and, finally, the whole became covered with a new epithelium, which had gradually spread from the edges of the wound. The tissues now became denser and offered more and more support to the body weight, until, as may now be seen, the boy has acquired a very useful limb and can walk without discomfort.

We must, therefore, infer that a metamorphosis into bone has taken place, and as the original diaphysis with its medullary structure is gone, we can find no osteogenic agent in the result other than the periosteum.

We must draw a similar conclusion from the recent case reported by Ceci: The patient, a young man, developed an acute osteomyelitis of the left scapula five days after circumcision for inflamed phimosis. One month later, Ceci[1] extirpated the bone, making the usual L-flap. The periosteum was left intact as far as possible, and the arm was preserved. The patient recovered rapidly, and there was a subsequent regeneration of the bone.

The only possible explanation of this result is by the hypothesis of periosteal agency or coöperation.

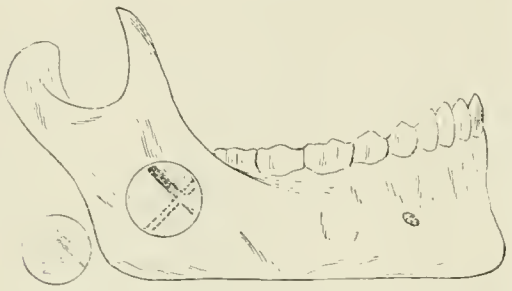
The following case is in confirmation of Macewen's proposition that "A portion of bone which has its continuity severed on all sides and has had all its periosteum removed is capable of living and growing." This is in contradiction of our inference in the case of the tibia and can be reconciled only by the assumption that the discovered laws of osteogenesis are of a lower order, subject to some general law of which we are as yet ignorant.

Mrs. L., aged forty-seven years, had suffered with a neuralgia of the maxillaris inferior, for the relief of which all medical means had been exhausted in vain, and

[1] Transactions of the Philadelphia Academy of Surgery, 1888.
[2] Loc. cit., p. 293.

[1] Centralbl. f. Chirurgie, Dec. 17, 1887.

which, therefore, left to Dr. Miller's option only the *dernier ressort* of neurectomy. The mode of operating was the usual one. The ramus was trephined near the angle of the jaw, the canal was exposed, and about two inches of the nerve trunk were drawn out and excised. The button was, however, returned after having been sterilized in a 1 to 1000 solution of corrosive sublimate, but it was not returned to its old position. With a view of imposing a barrier to the reproduction of the nerve, it was so rotated around its vertical axis that the groove upon its under surface stood at right angles to the axis of the canal. Not only did the wound close by first intention, but the button grew solidly in its position. Now, the curious thing in this case is, that before trephining he had carefully removed the periosteum, so that the latter can claim no part in the subsequent bone repair. After seven months there has been no return of the disease.



DR. JOHN B. ROBERTS said that it is a curious fact that the medical mind has not appreciated the possibility of bone production, despite the frequent instances that must always have come under notice. He was taught in cases of comminuted fracture, to take out the spicules of bone that were entirely separated from the larger fragments, lest they should necrose and give rise to trouble. Now it is the practice of the best surgeons to leave the spicules, and we find that often they do not die, and that they assist in the process of union and solidification. This experience is in the same line as the facts given by Dr. Miller in connection with his interesting case. If these spicules of bone can reunite, why not the button removed by trephining? Why is it not good practice to insert, when necessary, a portion of dog bone or chicken bone? as, indeed, has been done. We must not forget, however, the importance of asepsis, and that it is antiseptic surgery that has made these procedures possible.

In a case such as Dr. Miller reports, in which he rotated the button of bone, turning the groove in which the inferior dental nerve had run at right angles to its former direction, he should be inclined to go still further, and turn it upside down. The bottom of the pit in which it is to be placed, and the periosteal surface of the button being scraped, the ungrooved, freshened surface, formerly external, would then be placed inward, and a bony plug would be interposed between the divided ends of the nerve, probably preventing the reunion and the return of pain which so often occur.

The case of tibial resection was very interesting to him, as he had recently operated upon a similar one; the patient being, however, a woman of about fifty years, so that he cannot hope for as complete a closure of the cavity in the bone as in this growing child, exhibited by Dr. Miller. In that case, he removed the whole front of the tibia, going as near the articular cartilages above and below as he dared. The process of repair was like that we see in trees. We know that if a foreign body is inserted into a wound made in the trunk of a young tree, the process of cell growth will go on about it, and finally it will be completely covered in, and the presence be unsuspected, until, perhaps, the saw strikes it, as the tree is being converted into lumber.

DR. GEORGE E. STUBBS said that, in regard to operative treatment of neuralgia, we are entering upon a stage of work that will be much enlarged in the near future. He had a case recently in which neuralgia of the inferior dental nerve had existed for nearly seven years. He removed one and three-fourths inches of bone with the dental engine, took out as much of the nerve as he had access to and dressed and treated the wound antiseptically. The wound healed by first intention, and as yet there has been no return of pain; so that he considers he has obtained a very good result.

DR. NANCREDE said that the first question to be answered in a discussion of this kind is, What constitutes the periosteum? If we mean a fibrous membrane, the inner layer of which consists principally of yellow elastic tissue, then we must agree with Macewen's extreme views and admit that it has nothing to do with bone repair; but if we study the normal process of bone development, he, at least, must arrive at a different conclusion. The long bones are laid down in cartilage, a temporary structure. How do they ossify? By means of this very periosteum, which Macewen treats with such contempt, and which Ollier exalted too highly. There is a third layer of the periosteum in direct contact with the bone, and this layer is composed entirely of those elements which, wherever we see them, we recognize as the agents of ossification—the osteoblasts. The temporary cartilage is invaded by connective tissue ingrowths from the periosteum, covered with osteoblasts, and is eaten up by them; and we find it permeated and finally replaced by a network of fibrous tissue covered with osteoblasts. A certain number always remain beneath the periosteum. A certain number, very small, remain in the Haversian canals, a still larger number in the medulla.

It is clear to him why compact tissue dies; it has so few osteogenetic cells. The medullary tissue lives because it is comparatively rich in osteogenetic elements. Why does bone die when the periosteum is stripped off? Because the resulting inflammation is so severe that the inflammatory tissue strangulates the osteoblasts in the Haversian canals. With antiseptic means we now control the inflammation, and the osteoblasts are not killed, and the bone is saved.

We are very hard, nowadays, on the periosteum. The fibrous layer has nothing to do with bone repair, but its osteoblastic layer is in direct communication through the lining of the Haversian canals with the medulla; it is practically one structure; and thus, if we look at this matter from the standpoint of a correct histology, we find that both views are correct, provided only that we have a distinct understanding as to what is meant by the word periosteum in each case.

As to Dr. Miller's case, he cannot quite agree with him as to what formed the bone in the case of total excision of the diaphysis of the tibia. While the shaft was dying, new bone was formed by the deep layer of periosteum,

but after that the medullary spaces of the involucrum completed the bone.

He would also take exception to Dr. Roberts's proposition to scrape the button of bone and turn it inside out, in the case of trephining the jaw for neuralgia. By this process he would remove all the osteoblastic cells, and the compact tissue would have a very good chance of dying. One reason for failures in operations about the lower jaw is that it contains so little true medullary tissue, while, on the contrary, we can replace trephine buttons in the skull and have union, because the skull contains a large amount of such tissue.

The case of Dr. Agnew, referred to in the paper, occurred some twenty odd years ago. He saw the operation. The wound was completely covered by granulations. The fact that a denuded external table did not always necrose was known to Potts and to all the older as well as modern surgeons, and if Ollier had not led us astray by grafting, by insisting upon the periosteum being the sole osteogenetic agent, ignoring the fact that in removing it a layer of cells identical with those of the medulla are torn off, we would have arrived at a correct practice sooner; but surgeons went wrong by authority of Ollier, as they are now going wrong in the other direction by authority of Macewen.

In regard to the implantation of dead teeth, which Dr. Roberts referred to, the principle is probably the same as in the bony pegs formerly employed for ununited fractures. They are hollowed out by the granulation tissue, which develops into a fibrous or even osseous tissue and so holds the tooth in place by these newly formed digitations.

About twelve years ago he exhibited to this Society a case in which he resected four and a half inches of the humerus, and about two and a half inches were reproduced from the sawn end. This was without antisepsis. In the case referred to by Dr. Miller, in which he drilled the ulna, he was sure that the bone granulations fused with those of the soft parts for these reasons: the shell of bone when detached was not more than one-fourth the thickness drilled through, while the new bone was nearly as thick as the ulna of the other other side, as the cicatrix was not materially depressed. A recent experience, in a case of knee-joint excision, induced him to recommend that instead of wiring fragments of bone we nail them together, after having previously drilled or not, according to circumstances, allowing the heads of the nails to project through the skin. We thus save trouble and avoid damage in the removal.

Dr. Roberts said that Dr. Nancrede misunderstood him in regard to scraping away the cancellated tissue in reversing the plug in the case of trephining the lower jaw. He would scrape only what he calls the fibrous periosteum from the button, and from the bottom of the pit in the jaw he would take away the cancellated structure sufficiently to remove all trace of the nerve canal. The two raw surfaces would be placed together, and, by sinking of the button, would be a solid bony plug, interposed between the nerve ends.

Dr. Miller did not see any advantage in reversing the plug over rotating it. The groove being at right angles to the course of the nerve, the part in contact with the nerve is still solid bone, and the groove does not matter at all. In relation to the tibia case, the reason he emphasized the fact that the repair took place from the periosteum is because there was entire death of the old bone with the involocrum, and the periosteum did not die.

CORRESPONDENCE.

A VALUABLE REMEDY FOR CHRONIC DIARRHŒA.

To the Editor of The Medical News,

Sir: I think you would do a service if you would call attention in your journal to a valuable remedy for chronic diarrhœa.

Many years ago I suffered severely from that trouble; I considered it incurable. Being in Paris, one of the best physicians there assured me it could be cured by a diet of racahout, and it was.

Afterward here I found one could not get the acorn meal that forms the active part, but knowing that its usefulness must depend on the tannin it contains, I tried substituting it as follows:

Powdered chocolate, pure	½ lb.
Rice flour	½ "
Powdered sugar	½ "
Tannin	¼ oz. (120 grs.)

The tannin, or the rest, separately, have little effect. Together they restore the tone of the alimentary canal and nourish as well as cure.

One thing is *essential*, that is long cooking, not less than half an hour. If simply boiled a few minutes, the harsh taste of the tannin is very strong; with a good half hour's cooking, it disappears *wholly*—it is impossible to distinguish the medicine from ordinary broma. I think this has something to do with its curative powers and with the ease of digestion by the most irritable stomach. The remedy is too valuable not to be more widely known.

The amount to be taken is a teacupful morning and evening at meals.

Very truly yours,

M. C. L.

NEWS ITEMS.

The Harvard Medical School.—In addition to the existing requirements for the third-year degree, each candidate will be obliged to take examinations from a list of elective studies, to be chosen at the commencement of the year. He may choose to pass an examination ot two hours in either of the following subjects: dermatology, diseases of the nervous system, diseases of children or gynecology; or he may pass two examinations, of one hour each, in any two of the following subjects: ophthalmology, otology, mental diseases or legal medicine.

Dr. T. M. Rotch has been appointed Assistant Professor of Children's Diseases.—*Boston Med. and Surg. Journal*, July 26, 1888.

The Expenses of the International Medical Congresses.—Ewald, in the *Berlin. klin. Wochensch.*, July 9, 1888, in a brief historical sketch of the International Medical Congresses which have been held, prepared for the use of the Committee on the Organization of the Berlin Congress, concludes with the following statistics of the last four meetings:

Congress.	Members.	Printing, including Transactions.	Receipts from registration	Government appropriations	Private subscriptions.	Total cost of the Congress.	Cost per capita.
1879. Amsterdam	630	$1,875.00	$2,330.00	$1 040.00	$2,375.00	$5,775.00	$9.16
1881. London	3181	16,000.00	16,466.75	.....	28,620.00	43,695.00	13.73
1884. Copenhagen	1400	5,650.00	7,062.00	14,125.00	14,075.00	18,362.50	13.30
1887. Washington	2500	18,400.00	31,696.00	10,000.00	12,054.75	54,125.00	21.65

At London a guarantee fund of $5750 was raised, but not used.

These figures are not absolutely accurate, but they are approximately correct, and show how the expenses of the Congresses have grown, and they afford a basis of comparison for other meetings.

The Royal College of Physicians.—On the 27th of June, the President of the Royal College of Physicians, Sir Andrew Clark, received a large and distinguished company in the hall of the College. An interesting collection of works of art and curiosities was on view for the entertainment of visitors. Especially interesting to medical men, who, of course, formed the great majority of the gathering, was the diploma of Harvey, the discoverer of the theory of the circulation of the blood. It was from the University of Padua, and is dated April 25, 1602. There were also a manuscript book in the handwriting of Jenner, a number of relics of Dr. Priestley, many autographs of medical celebrities and some scientific exhibits. The band of the Royal Artillery, under the Cavaliere Zavertal, played a selection of popular music during the evening.—*Lancet*, July 7, 1888.

A New Breast Pump. — Auvard has invented a new breast pump, described by recent French journals, which consists of a glass bell fitting over the breast, from which a tube goes to the child's mouth, and a second and larger tube to the mouth of the mother. The mother aids the child by performing suction simultaneously with the child.

Berlin Druggists and Bogus Prescriptions.—It is said that a Berlin society sent out a long series of bogus prescriptions, containing, for example, "tuber cinereum," "urticaria rubra," "pemphigus foliaceus." These things were dispensed and paid for in over sixty Berlin drug stores.—*Brooklyn Med. Journal*, June, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 31 TO AUGUST 6, 1888.

MAGRUDER, D. L., *Surgeon* (U. S. Army).—Is granted one month's leave of absence, to take effect on or about August 13, 1888.—Par. 11, *S. O. 171, A. G. O.*, July 25, 1888.

WOLVERTON, WILLIAM D., *Major and Surgeon* (U. S. Army).—Is relieved from duty at Washington Barracks, District of Columbia, and ordered to duty at Fort D. A. Russell, Wyoming Territory.—Par. 13, *S. O 173, A. G. O.*, July 27, 1888.

GARDNER, WILLIAM H., *Major and Surgeon* (U. S. Army).—Is relieved from duty at Fort McHenry, Maryland, and ordered to duty at Washington Barracks, District of Columbia.—Par. 13, *S. O 173, A. G. O.*, July 27, 1888.

CALDWELL, DANIEL G., *Major and Surgeon* (U. S. Army).—Is relieved from duty at Fort D. A. Russell, Wyoming Territory, and ordered to duty at Jefferson Barracks, Missouri.—Par. 13, *S. O. 173, A. G. O.*, July 27, 1888.

WHITE, ROBERT H., *Surgeon* (U. S. Army).—Is relieved from duty with the Battalion of the First Infantry, at Santa Barbara, California, and will proceed to Angel Island, Cal., on public business, on the completion of which he will stand relieved from duty in this Department.—Par. 4, *S. O. 43, Headquarters Department of California*, July 17, 1888.

MUNN, CURTIS E., *Assistant Surgeon* (U. S. Army).—Will proceed to Santa Barbara, California, and report for duty to the commanding officer of the First Battalion of Infantry.—Par. 3, *S. O 43, Headquarters Department of California*, July 17, 1888.

BYRNE, CHARLES B., *Captain and Assistant Surgeon* (U. S. Army).—Is relieved from duty at Washington Barracks, District of Columbia, and ordered to duty at Fort McHenry, Maryland.—Par. 13, *S. O. 173, A. G. O.*, July 27, 1888.

COCHRAN, JOHN J., *Assistant Surgeon* (U. S. Army).—Will proceed to Benecia Barracks, California, on public duty, on completion of which he will return to these Headquarters.—Par. 1, *S. O. 44, Headquarters Department of California, San Francisco, Cal.*, July 20, 1888.

EWING, CHARLES B., *First Lieutenant and Assistant Surgeon* (U. S. Army).—Is relieved from duty at Fort Lewis, California, and ordered to duty at Washington Barracks, District of Columbia.—Par. 13, *S. O. 173, A. G. O.*, July 27, 1888.

JARVIS, N. S., *Assistant Surgeon* (U. S. Army).—Is granted one month's leave of absence on surgeon's certificate of disability, with permission to go beyond the limits of the Department.—Par. 1, *S. O. 90, Headquarters Department of the Missouri.*

JOHNSON, HENRY, *Captain and Medical Storekeeper* (U. S. Army).—Leave of absence granted for one month and fourteen days, from August 1, 1888.—*S. O. 170, Headquarters of the Army, A. G. O.*, July 24, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JULY 28, 1888.

PENROSE, THOMAS N., *Surgeon.*—Detached from the Navy Yard, Boston.

PARKER, J. B., *Surgeon.*—Ordered to the Navy Yard, Boston.

MCCORMICK, ALBERT MCD.—Commissioned Assistant Surgeon in the Navy.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JULY 28, 1888.

MURRAY, R. D., *Surgeon* —To proceed to Manatee, Florida, on special duty, July 21, 1888.

WASDIN, EUGENE, *Passed Assistant Surgeon.*—To proceed to Key West, Florida, for temporary duty, July 21, 1888.

FATTIC, J. B., *Assistant Surgeon.*—To proceed to Memphis, Tenn., for temporary duty, July 28, 1888.

WOODWARD, R. M., *Assistant Surgeon.*—When relieved, to proceed to Boston, Mass., for duty, July 24, 1888.

GOODWIN, H. T., *Assistant Surgeon.*—When relieved, to proceed to Cincinnati, Ohio, for duty, July 24, 1888.

GUITERAS, G. M., *Assistant Surgeon.*—Appointed an Assistant Surgeon July 23, 1888. Assigned to duty at the Marine Hospital, New Orleans, La., July 24, 1888.

HUSSEY, S. H., *Assistant Surgeon.*—Appointed an Assistant Surgeon July 23, 1888. Assigned to duty at the Marine Hospital, Baltimore, Maryland, July 24, 1888.

ORIGINAL LECTURES.

THE CEREBRAL PALSIES OF CHILDREN.

Clinical Lectures delivered at the Infirmary for Nervous Diseases.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, PHYSICIAN TO THE PHILADELPHIA AND UNIVERSITY HOSPITALS AND TO THE INFIRMARY FOR NERVOUS DISEASES.

LECTURE V.

PATHOLOGY AND TREATMENT.

PATHOLOGY.—Varied as is the anatomical condition, the lesions have this in common—interference with the motor centres or with the conducting paths of the cerebrum. In reviewing a large number of post-mortem records, or in studying such a series of brains as that prepared by Dr. Wilmarth, at Elwyn, we are impressed, on the one hand, with the extent to which sclerotic and other changes may exist without symptoms if the motor areas are spared, and, on the other hand, with the degree of permanent disability which may exist with even slight affection of this region. Our knowledge is so limited to the appearances and states years after the onset of the symptoms, the final results of initial processes long past, that we are scarcely in a position to discuss accurately, in all its aspects, the pathology of this interesting group of cases. It is something, however, to get an outline for our ignorance and to ascertain in which direction facts are needed to sustain, or, it may be, to upset our theories.

A certain number of the cases of hemiplegia in children are due to *hemorrhage* from causes identical with those which prevail in the adult, and I have given illustrative instances of true apoplexy with laceration of the cerebral substance; but we may conclude safely, I think, that hemorrhage is not the common cause and accounts for a very small percentage. A small proportion of the cases of hemiplegia comes under the designation of birth palsies, as we have history of persistence of the paralysis from birth, and of the occurrence of difficult labor, often necessitating the application of forceps. In the cases of birth palsy which result usually in bilateral hemiplegia or paraplegia, the evidence points strongly to meningeal hemorrhage as one of the chief causes of the disorder. The great majority of these, as we have seen, present, at birth, one of two conditions, asphyxia or convulsions. The children are resuscitated only after prolonged attempts at artificial respiration; more commonly convulsions occur, either immediately after birth, or within the first ten days of life. Facts have been gradually accumulated to show that hemorrhage, usually meningeal, is a very frequent condition in children dying shortly after birth of asphyxia or convulsions, and as the birth palsies almost invariably have this history it seems reasonable to conclude that, in the cases which recover and subsequently present signs of motor disturbance, a similar, though less intense, lesion has existed.

Apoplexia neonatorum is by no means an uncommon event. Little fully understood its importance and quotes from Cruveilhier, Evory Kennedy, Hecker and Weber to show the occurrence of meningeal hemorrhage and capillary extravasations in newborn children. In 1880 Litzmann[1] communicated the results of the examination of 161 newborn children, in 81 of whom the spinal canal was exposed. There were 35 instances of meningeal hemorrhage, in 19 the extravasation being in considerable amount. The exudation existed in both cerebral and spinal meninges.

Parrot,[2] in 34 cases of cerebral hemorrhage in the newborn, found 5 in which the blood was in the cavity of the arachnoid and 26 in the subarachnoid space. In a large proportion of the cases the extravasation was bilateral. This author makes no allusion to the association of the lesion with abnormal labor.

Dr. Sarah J. McNutt has reported ten cases[3] and her paper is very convincing as to the frequent association of this condition with abnormal labor and with asphyxia and convulsions in the newborn. It may occur when the parturition has been normal, and may be deferred some days, or even weeks, as in the following case, which occurred in Dr. Parvin's Wards at the Philadelphia Hospital, and the specimens from which I saw with Dr. Stahl.

Child æt. six weeks, mother single; labor normal. Remained healthy until the forty-fifth day, when at 8 A. M., it had a convulsion, at first on the right side and finally general. Convulsions were repeated through the day and an ecchymotic rash appeared on trunk and extremities. Death at 10 P. M. The post-mortem showed extensive meningeal hemorrhage, a large clot over the cortex, particularly on the left side. There was much more blood in the left than in the right Sylvian fissure, and it extended under the frontal convolutions; it looked as if the bleeding had begun here, but the most careful examination of the vessels showed no changes in the arteries or thrombi in the veins. There were clots also in the posterior and middle fossæ, and a uniform sheeting of coagulated blood extended beneath the spinal dura.

I saw a second case, this winter, at the Philadelphia Hospital, and I am indebted to Dr. Hirst, who made the autopsy in both these cases, for the following notes: Case of twins; first child delivered with forceps—head presentation. The second child presented the breech, and there was great difficulty in the extraction of the head, required much force. Twenty minutes after birth, left lateral convulsions occurred and were repeated at intervals. The child lived forty-eight hours, having become intensely anæmic. The post-mortem showed

[1] Archiv f. Gynäkologie, Bd. xvi.

[2] Clinique des Nouveau-nés, Paris, 1877.

[3] American Journal of Obstetrics, 1885.

the viscera normal. The brain, in places, was remarkably soft, the tissue almost diffluent. A large clot existed beneath the dura mater on the right side, very thick over the cortex. It dipped into the fissures and sulci and extended down the cord. About the middle of the longitudinal sinus there was an irregular laceration, several lines in length.

The extravasation has in many cases been thickest over the motor areas, and from what we know of the changes which time may effect in effused clot, there is nothing inconsistent in the belief that sclerosis from compression or porencephalus from destruction might ultimately result. Gowers advocates this view in the case of the birth palsies, which, indeed, he considers in his work under the heading of "Infantile Meningeal Hemorrhage." Probably all the cases cannot be assigned to this cause, and I think, with Jacobi,[1] that certain of them may be due to fœtal meningo-encephalitis. Certainly in Ashby's case,[2] in which, in a child twenty-two months old, the cortex was smooth, without a trace of convolutions, the sclerosis must have begun during embryonic life.

The frequency of spinal hemorrhage renders it not improbable that some of the cases of spastic paraplegia may be due to this cause; and Ross suggests that as traction in feet presentation has been known to tear the cord, slighter degrees might injure the pyramidal tracts, and lead to a sclerosis.

We have then in the spastic diplegia, and in a few cases of hemiplegia—the true birth palsies—information which enables us to assign to hemorrhage an important *rôle*. More positive knowledge may ultimately be obtained by the dissection of cases at different ages after the onset.

When we turn to the cases of infantile hemiplegia, which come on during the first two or three years of life, we are met at once with conflicting theories. It is well to bear in mind that we are called upon to explain the mode of origin of sclerosis and porencephalus, the two conditions present in the great majority of the cases. A certain number of cases of infantile hemiplegia are due to hemorrhage, to embolism and aneurism, a few to tumor, as glioma or chronic tubercle; but, as we have seen, these form a fractional part. We require to know the pathological process lying at the basis of the convulsive attacks with coma, which come on suddenly, or after a slight febrile movement, frequently succeed an infectious disease, and leave a hemiplegia with too often its disastrous sequences—epilepsy and imbecility. In a large proportion of the cases the disease is such a clinical unit, with symptoms as marked and definite as those of infantile spinal paralysis, that we might expect a corresponding uniformity in the anatomical lesion. Unfortunately we are, so far as I can ascertain, entirely without information upon the state of the brains of children dying during or shortly after the attack; and the question resolves itself into an explanation of the conditions most commonly met with years after the onset, viz., sclerosis and porencephalus.

A few years ago Strümpell[3] suggested that the lesion was the cerebral counterpart of the infantile spinal palsy, a *poliencephalitis* of the motor areas of the cortex, analogous to the poliomyelitis of the anterior horns. The two affections are very similar in the mode of onset, in the age affected and in the liability to follow one of the infectious diseases. The more frequent occurrence of convulsions and the more prolonged coma might be expected from the seat of the disease. This very plausible and suggestive view has not met with much favor, not so much, I think, as it deserves. Against it has been urged the absence of anatomical facts, but this defect it shares with several theories. I see no improbability in the view; and it is possible that we shall have, ere long, the necessary anatomical facts to support it. The forms of encephalitis which we know: Virchow's encephalitis of the newborn; the miliary encephalitis due to septic causes, such as has been found in diphtheria and in aphthous stomatitis; and the steatosis of Parrot, arise under different circumstances, and do not present the symptoms of these cases of infantile hemiplegia. J. Lewis Smith has suggested[1] that certain of these cases of infantile hemiplegia are due to cortical encephalitis, set up by the poison of cerebro-spinal fever.

The frequency with which the disease is associated with or follows one of the infectious diseases is suggestive. Endocarditis is not rare in scarlet fever, measles and diphtheria, the affections which most commonly precede the hemiplegia, and embolism may account for a certain number of these cases. In diphtheria there may be plugging of the smaller cerebral arteries with micrococci, without the occurrence of endocarditis. There is another way in which the relation of the infectious diseases may be regarded. We know that in certain fevers, typhoid particularly, changes have been met with in the smaller arteries leading to anæmic necrosis in the corresponding districts. This has been worked out in the heart by Landouzy and Siredey,[2] and if it occurs in limited areas of this organ it might also take place in the brain. From what we know of sclerosis in other organs, notably the heart, the *rôle* played by the bloodvessels in the process is all important. Kundrat has already suggested that porencephalus results from an anæmia of definite areas corresponding to arterial distribution, but without arterial lesion. It is difficult to conceive of such a condition, but a widespread endarteritis, similar to, but more extensive than that which is known to induce anæmic necrosis of the heart-muscle might initiate a sclerosis; or, if the obstruction was suddenly effected, and large vessels involved, produce a rapid necrosis, the final changes of which would represent porencephalus. That this latter condition results from vascular obstruction we have evidence in the large defects which are occasionally found in brains of adults, and in the one organ there may be regions of softening in all stages of regressive change. Less abrupt processes in smaller vessels may account for certain of the cases of sclerosis, and the changes which Martin, Sabourin and other French writers have found in the smaller arteries in cirrhotic regions, make it by no means improbable that the cerebral counterpart has also a vascular origin.

Jendrássik and Marie[3] have described vascular lesions in cerebral sclerosis, which they believe to be primary.

[3] Archiv de Physiologie, 1883.

The change is in the perivascular region, which is greatly increased in size and intersected by connective tissue growth, which is in intimate relation with the vessel wall and with the neuroglia. While regarding the periarteritis as the primary change in the cerebral paralysis of children, these authors do not exclude embolic and thrombotic processes in the smaller vessels. They refer also to the connection of these with infectious processes.

In a third way, too, an infectious disease might induce hemiplegia, by causing changes in the cerebral motor centres similar to those which occur in the disseminated myelitis following measles and scarlatina. We have not had until recently much positive knowledge of the latter, but such a condition as Barlow[1] has described in the cord shows the direct influence of the specific poisons on the elements of the gray matter. May not this occur in the motor cells of the cortex as well as those of cord? But here we return to Strümpell's view. The changes in the gray matter are, in most of these instances, necrotic, rather than inflammatory, and the vascular lesion is the primary one. In his researches in sclerosis Adamkiewicz[2] found the destruction of the nerve elements the first step in the process, to which the proliferation of the neuroglia was secondary.

In favor of the embolic theory it may be urged that the affected areas correspond with definite territories. Of porencephalus this is to a great extent true, but not always of sclerosis, which may be most irregularly distributed. I purposely noted, when discussing the morbid anatomy of sclerosis, the districts involved in the ten specimens in the Museum of the Elwyn Institution. The involvement of two or three regions, far apart from each other, the frequency with which the territory of the posterior cerebral artery is the seat of the sclerosis are against embolism as a cause.

Gowers has suggested that the lesion in these cases is, *thrombosis* of the surface *cerebral veins*, a well-recognized condition in children, which sets in with convulsions. Usually there is sinus thrombosis as well. Certainly, there are no veins in the body so favorably situated for the coagulation of blood; "they are roomy in proportion to the amount of blood they carry, they are tortuous and abundantly anastomosing, so that the current of blood is almost reversed at some points and can easily stagnate" (Edes).[3] Gowers quotes a case of Money's in which the thrombosis occurred after scarlet fever. Handford[4] has reported the case of a boy aged five years, in whom the cerebral veins were like whip cords, and there was hemorrhage on the surface of both hemispheres. There was also sinus thrombosis. The symptoms, however, were not those of infantile hemiplegia. Parrot[5] states that this condition is very common and in Plate IV. of his work there is a beautiful illustration of thrombosis of the surface veins with hemorrhage. The advantage of this view is that we are dealing with recognized lesions, of common occurrence in infancy, capable of explaining satisfactorily the symptoms; and yet the proof is lacking, the demonstration of its existence in one of these cases of infantile hemiplegia has still to be made.

[4] British Med. Journal, 1887, i. p. 1098. [5] Loc. cit.

To sum up: Infantile hemiplegia is probably the result of a variety of different processes, of which the most important are:

(1) Hemorrhage, occurring during violent convulsions or during a paroxysm of whooping-cough.[1]

(2) Post-febrile processes: (a) embolic; (b) endo- and peri-arterial changes; and (c) encephalitis.

(3) Thrombosis of the cerebral veins.

There are several problems of interest in connection with the pathology of infantile spastic paraplegia. Of special importance is the condition of the pyramidal tracts in the cord, and the attention of future observers should be directed to this point. In three cases of spastic diplegia and in the one case of spastic paraplegia there was descending degeneration. In Ross's case the cord was normal. In Ashby's case was the change in the pyramidal tract truly a degeneration, or was it not rather arrest of development? Most probably the latter, in connection with a brain the cortex of which was smooth and presented no trace of convolutions. In Ross's case though the cord was said to be normal, yet the anterior pyramids were not more than half the normal size, and the lateral columns were smaller. Alexandra Steinlechner[2] has reported the case of a lad, named Post, æt. six years, helpless from birth. The legs were in equinovarus position, but as there was no note of the condition of the arms, I did not know in which category to place the case; it was probably one of spastic diplegia. Post-mortem, bilateral porencephalus was found; the lateral tracts were undeveloped and did not contain more than one half the normal number of nerve fibres. Hervouet[3] has recorded the case of an idiotic child, æt. three and a half years, without spasms or contractures, in which there was a condition of microcephalus with complete absence of development of the pyramidal tracts in the cord. The motor strands in the cord do not attain their full development until after birth, according to Hervouet not until the third or fourth year. It is a question of no little interest to determine the exact condition of these tracts in cases of diplegia and paraplegia of children. Sharkey[4] states that in cases of congenital absence of the whole or part of the motor centres of the brain, which are accompanied by contracture, the pyramidal tract has proved to be deficient. And yet in Hervouet's cases these strands were undeveloped without any spasm of the muscles. It would really appear then that actual sclerosis of the lateral tracts is not an essential condition of spastic rigidity though present in a great majority of the cases. In the adult in the cases of Schultz,[5] Strümpell[6] and Anna Klumpke,[7] the pyramidal tracts have been found normal in spastic paralysis, and Blocq[8] in his recent monograph acknowledges that contractures may exist without affection of these parts. The problem of rigidity is by no means an easy one to solve. The over-action of the spinal centres seems the most reasonable view, at

[1] Dr. Samuel West reported a case of this kind to the Clinical Society of London last year. Medical Press and Circular, 1887.

one time conditioned by the suppression of the function of the pyramidal tracts, the absence of inhibition, the "let go" theory of Hughlings Jackson, at another possibly excited reflexly, even when the motor strands in cords are intact.

We shall need in future autopsies on cases of spastic paraplegia in children specific details as to the condition of the lateral tracts, and particularly as to degeneration or absence of development. The two conditions might readily be confounded as can be gathered from an examination of the plate which illustrates Hervouet's paper.

Treatment.—In the majority of the cases the physician is called at the onset to treat an attack of convulsions or of coma, developing suddenly or after a few days' indisposition, or following, perhaps, one of the fevers. The paralysis is not apparent until the active symptoms have subsided, though if the convulsions are severe and unilateral it may be anticipated. These symptoms demand the bromides with chloral, a calomel purge, cold to the head, and, if necessary, leeches. The cases resemble so closely the ordinary convulsions of infancy associated with teething that the development of so serious a condition as hemiplegia is a great shock to the parents, who are very apt to blame the physician for having done too much or too little. In such an accident following vaccination the doctor is fortunate indeed if he escape unjust criticism. In the birth palsies, unless there are marks of the forceps, the condition of the limbs of the child does not attract attention, and it may be weeks or months before the disability is discovered.

The traumatic cases, such as the three reported, suggest surgical interference, two of them at any rate, as they were doubtless due to hemorrhage; but it is well to remember, in these days of safe surgery, that in children traumatic hemiplegia may sometimes disappear completely in a few days. I reported an instance some years ago[1] of a child, æt. twenty-three months, who had fallen from a balcony, and was admitted to my wards with a large hæmatoma of the scalp, left hemiplegia and coma. The symptoms gradually disappeared and the child made a complete recovery. A case was narrated to me by Dr. Murray Cheston of a child who was tripped by his brother and fell on his head. No external wound and no fracture. Hemiplegia developed, but in a few days disappeared completely and the boy is now quite well.

When the paralysis is established medicines are rarely called for, and the indications are to favor the natural tendency of the hemiplegia to improve and to lessen the rigidity and contractures, and, if necessary, overcome them by mechanical or surgical measures.

While it is impossible to predict, in any given case, to what extent the original palsy will disappear, we can usually expect a return of power in the leg and face, incomplete in the former, often perfect in the latter. In rare instances, two only in the series of one hundred and twenty cases, did the paralysis entirely disappear. The residual palsy is most marked in the upper extremity, and even when the arm is tolerably useful the fingers do not regain the power of delicate movements. Temporary arrest of growth and some degree of atrophy follow invariably, but as the child grows up we rarely see the great discrepancy in size of members which is common after the spinal infantile palsy. To maintain the nutrition of the paralyzed parts we employ warmth, massage and electricity. The temperature of the affected members is usually lowered and the circulation sluggish, so that the limbs should at first be wrapped in cotton-wool, and when the patient begins to make efforts at walking, flannel underclothing should be used. Attention to this apparently minor point should be impressed upon the mothers; it is too often neglected. Massage of the paralyzed muscles should be practised daily. Simple directions should be given to the mother or nurse, in the absence of a professional rubber. The chief point is to manipulate the muscles thoroughly, and I usually order the rubbing to be done with sweet oil, morning and evening for twenty or thirty minutes. I have strong belief in the efficacy of this treatment in keeping up the nutrition of the enfeebled muscles. To be of any service the applications must be continued for months.

Electricity is probably of no service in the original lesion, which may be left to nature, undisturbed by galvanism, which has been recommended by some authors. Of positive benefit is faradization of the paralyzed muscles, which must, however, be carried out persistently for months. Next to the rubbing, it is the most important agent upon which we rely to prevent atrophy and maintain the nutrition of the parts. It is not often that we find hospital patients able to spare the time for the prolonged treatment needed in these cases. Fortunately, the wasting is not extreme, and even without the treatment the leg and face recover more or less completely.

A considerable number of the cases come under observation when there are marked rigidity and contractures. For this condition in the palsied arm of hemiplegia not much can be done, but in the cases of spastic diplegia and paraplegia manipulations and surgical measures will often enable a crippled patient to walk. Persistent massage with strong flexion and extension of the limbs, as recommended by Dr. Weir Mitchell, is of great service. Case IX. of the spastic paraplegia cases could not walk when brought to the Infirmary, and after about a year's persistent treatment, frictions with oil and forcible flexion and extension, she can now get about the house quite well. Sooner or later the majority of these cases come under the care of the orthopedic surgeons who were dealing with this condition—and some indeed, as Heine, knew upon what it really depended several decades before physicians had recognized that it was primarily an affection of the nervous system. The wood-cuts and plates given in the works of Heine, Little and Adams show how well they dealt with these cases, and we have many illustrations at the clinics of my colleagues, Drs. Morton, Hunt and Goodman, of the good results of division of tendons and of the application of proper apparatus.

There are one or two special symptoms calling for comment. The aphasia, as we have seen, usually disappears, but it may be helped by systematic education, and these cases do better and recover more promptly than aphasia in the adult.

Epilepsy is a distressing symptom for which many of the cases seek relief. It is well to recognize clearly the cortical nature of the attacks, and let the parents know that a cure can rarely be anticipated. It is encouraging, however, to note that the seizures may lessen greatly,

[1] Canada Medical and Surgical Journal, vol. viii.

and prolonged periods of quiescence are not uncommon. The attacks of hemi-epilepsy without loss of consciousness may persist for years before a general convulsion with loss of consciousness occurs. In some instances the attacks are repeated with extraordinary frequency, twenty or more daily. In the transient attacks of *petit mal* the bromides do good; but, as a rule, in the true Jacksonian fits, unless there is much irritability and excitement, I have not found them very beneficial.

An important question of practical moment has arisen in connection with the propriety of surgical interference in these cases. Jacksonian epilepsy has now its surgical aspects, and there have already been several successful cases of removal of tumors from the motor areas of the cortex. Infantile hemiplegia offers some of the most typical instances of cortical epilepsy, and it may be well to consider how far it is likely that surgical interference can here be successful. As we have seen, in the review of the morbid anatomy, the conditions to be dealt with are (1) apoplectic, embolic or thrombotic foci, which are as frequently in the territory of the central as of the cortical arteries; (2) sclerosis; and (3) porencephalus. I do not think that, in any of the cases which I have reviewed, the anatomical condition offered the slightest possibility of relief from surgical interference. I except the case of glioma of the paracentral lobule to which I referred. This girl had had Jacksonian epilepsy for many years and the tumor could have been readily removed. In the second autopsy of the Elwyn cases, in which there were blocks of sclerosis, the mass causing the hemiplegia might have been removed, but there were several other areas. There have been two cases of operation in the cortical epilepsy of infantile hemiplegia. Bradford, of Boston, operated on a case of Bullard's.[1] A boy, aged four years, forceps delivery, idiotic, and in a state of right spastic hemiplegia. There was a scar and depression on the right parietal bone, due probably to the forceps. The trephine was first applied over this part, but the brain-substance beneath was found normal. The left side was then trephined and a porencephalous condition of the Rolandic region found. The child died the next day. No autopsy was allowed. The other case was operated on in the Infirmary, by Dr. Morton. I have referred to it when speaking of the symptom of epilepsy (Case XCVII). Dr. Mitchell, under whose care the child was, believed there was a possibility that the lesion might be a localized area in the motor zone, which could be removed, and in this opinion Dr. Sinkler and I concurred. Accordingly Dr. Morton exposed the Rolandic region and found an œdematous condition of the membranes, but no focal disease. Whether the portion removed is sclerotic has not yet been determined. The child recovered perfectly from the operation, the dressings were removed on the sixth day. The spasm of the arm has lessened and the attacks of epilepsy have reduced in frequency.

There are several circumstances which militate against the probable success of operations of this kind. The nature of the lesion is such that not much can be anticipated. When sclerosis exists the area is usually too large for removal; when porencephalus is present, we are not, as Dr. Morton Prince said in the discussion on Dr. Bullard's case, "likely to improve a pure paralysis, due to a hole in the brain, by making the hole bigger." But a more serious objection was raised in the same discussion by Dr. J. J. Putnam, viz., the existence in these long-standing cases of descending degeneration. The paralysis in such instances could not be benefited, and it is only in exceptional instances that we can expect the epilepsy to be relieved. Time alone will determine how far in the removal of centres for cortical epilepsy the improvement is temporary or permanent, and how much less irritating the scar of a surgical wound will be than the cicatrix of an accidental trauma.

More serious in many respects, and more distressing to friends and relations, are the mental defects so apt to be associated with these cerebral palsies. The subjects of bilateral hemiplegia are usually imbecile, often idiotic; the spastic paraplegic cases offer greater hope of mental improvement, and many of the patients are intelligent and learn to read and write. They rarely suffer from epilepsy, so potent a factor in inducing mental deterioration. A large percentage of the cases of hemiplegia grow up feeble-minded, a larger percentage than indicated in our table. Much depends, no doubt, upon the area and regions of cortex involved, but even in such localized lesions as that shown at Fig. 1, there may be serious mental deficiency, showing that the actual damage is more apparent. The injury to the brain is usually done at the very time when the faculties are developing and the education of the senses is preparing the way for the higher intellectual processes. It is not surprising that in so many cases the damage is irreparable and that idiocy or imbecility results. A few years ago these cases were neglected and thought incapable of education. The results which are attained by Dr. Kerlin and his staff, at the Pennsylvania Institution for Feeble-minded Children, and in other public and private establishments, demonstrate that the lesson which Dr. Seguin, Sr. labored a long life to teach has been well learned—the lesson that with patient training and kind care many of these poor victims may be rescued from a condition of hopeless imbecility and reach a fair measure of intelligence and self-reliance.

ORIGINAL ARTICLES.

A CASE OF LIGHTNING SHOCK WITH RECOVERY.[1]

REPORTED BY J. B. PAIGE, V.S.

With remarks.

BY FRANK BULLER, M.D., M.R.C.S. ENG.
PROFESSOR OF OPHTHALMOLOGY IN M'GILL UNIVERSITY;

AND

T. WESLEY MILLS, M.A., M.D.,
PROFESSOR OF PHYSIOLOGY IN M'GILL UNIVERSITY, MONTREAL.

REPORT OF THE CASE. (BY J. B. PAIGE.)

The accident about to be described occurred in Prescott, Massachusetts, during a terrific thunderstorm, July 29, 1887, about five o'clock P. M.

Lightning struck the house, to all appearances the chimney of the upright part first. At the roof the current divided into three parts, one following the chimney down to the floor of the second story, then passed along a stove-pipe out of the chimney, and

[1] Read before the Medico-Chirurgical Society of Montreal, March 16, 1883.

partly to a nail in the floor by the legs of the stove, and thence by the timbers to the earth. A second subdivision of the current followed a rafter on the north side of the roof, after leaving which it could not be traced. This rafter was completely torn from its place. A third current passed down a rafter on the south side of the roof. At the lower end it divided again, one portion following the finish of the roof, passed along the other side of the L to the opposite corner, followed the track of a rolling door and reached the earth by the corner post of the house. The other part coursed along the studding of the house, near the window, and passed to the earth. Attached by a screw to the upper casing of the window was a large iron hook on which was suspended, by a brass chain, a bird-cage. One part of the current going by this chain to the bird-cage, left it at one corner, entered the body of the subject of the accident, and left the room by a nail in the floor.

That the electrical influence in this quarter was intense is proved by the fact that the links of the chain, in some places, were nearly melted apart, while the solder at the corner of the cage, where the fluid left, was completely melted. Again, the nail by which it passed through the floor was considerably roughened. It appeared as if it had been partially melted at a high temperature.

The position of the four persons about the place at the time the house was struck is represented by the letters A, B, C, D, the first three being out of doors, seated upon the floor of the piazza. D, through whom the electricity passed, was seated just inside the window.

The distance from A to B was about two feet, from B to C eighteen inches or two feet, and from C to D six or seven feet. As a result of the shock D was rendered completely insensible, C was thrown upon the floor and was unconscious for a second, in fact did not even hear the report, which was like the peal of heavy artillery. Although C and D were so much affected, neither A nor B felt the shock.

This all took place before one could realize what had happened.

A, B and C, who regained consciousness immediately, ran from the house about twenty or twenty-five feet upon the lawn. Thinking of their companion inside, they returned and found that she had been thrown from the chair in which she was sitting directly across another chair, a distance of two or three feet. She was taken out to the piazza immediately, and her condition was found to be as follows: Completely unconscious; motionless; muscles relaxed; left eye closed, right, open: face purple; pulse at wrist imperceptible; neither heart sounds nor respiratory murmur to be heard.

Later, an examination showed the course of the electric current to be as follows: It struck the head above the left eye, midway between the eyebrow and hair, which was apparently the part nearest the corner of the bird-cage; passed along in front of the ear, then to the central line of the thorax, descending by the stocking supporter, which was attached to the corsets; thence to the top of the stockings, leaving marks upon both limbs, but more especially upon the left, on the back of which, just above the knee-joint, was a burn about the size of one's hand. It had the appearance of an ordinary burn, and was only superficial. No trace of the current could be detected again until the foot was reached, from which it passed off by the joint of the great toe, tearing a place about two inches in diameter in the stocking and slipper, but not leaving the slightest mark upon the skin. With the exception of the burned spot on the posterior part of the left leg and one or two small burns on the body and the right leg, hyperæmic lines, alone, marked the course of the electricity in its passage over the body.

After removal of the patient to the piazza, the clothes about the neck and chest were loosened and artificial respiration commenced. In from three to five minutes the first sign of life appeared in the flexion of the right leg. The dark color disappeared from the face and the pulse could be felt at the wrist. It was then weak, rapid and irregular. The treatment was kept up for ten or fifteen minutes, until the body began to feel cold, when the woman was removed to the house and placed upon a bed. The moving caused a disturbance of the circulation, as was shown by the pulse, which became very faint and fluttering. In order to encourage the circulation, hot fomentations were applied to the chest, and as soon as they became cold were replaced by fresh ones.

Soon a new train of symptoms set in. There was difficult respiration. The mucus and saliva, which were very abundant, had gravitated back, and could not be swallowed because of complete paralysis of the pharynx, etc. There was, in fact, paralysis of almost all the muscles of the uppermost parts of the body, including the arms. The symptoms were those exhibited by an animal when being asphyxiated: violent muscular contraction, difficult and forced respiration, etc. To remove the saliva and mucus, which caused the obstruction, the head and trunk were lowered. Handkerchiefs were also used. These were placed over the finger and passed back as far as possible into the throat, and in this way large quantities of the saliva and mucus were gotten away.

From one-half to three-quarters of an hour after the accident, consciousness began to return and the muscles of the arm to regain strength. Sight was restored to the right eye, although it could not be moved. Though the subject could hear she could not speak. This was shown by the fact that when asked to press the hand if she felt better she responded. About this time paralysis began to disappear gradually from the tongue. Improvement continued: brief intervals of sleep were enjoyed through the night, and there was absence of any considerable pain.

The next morning, about twelve hours after the accident, there was sufficient œdema of the upper and lower lids of the left eye to close them completely; this lasted for several days, and when it disappeared there was noticed a slight effusion in the anterior chamber (?) which interfered considerably with vision. There were no signs of inflammation

of any of the parts of the eye. There was a complete return of the cerebral functions, the mind being as clear and as active as usual.

The patient could, as yet, swallow only a few drops of ice water at a time, and then with great difficulty. The trouble seemed to be in the pharynx, as it was easy enough to carry the water backward.

The paralysis passed away slowly, so that in about two weeks solid food could be swallowed. The strength of the patient was maintained during this period by thin gruels, brandy and a fluid preparation of beef (Bovinine).

To allay the great thirst of the first twelve hours, small pieces of ice were kept in the mouth.

Twelve or fourteen hours after the accident, intense pain set in about the head, neck, arms and chest. That about the chest continued during the day, but was somewhat relieved by mustard poultices. The pain in the head was constant and very severe, and lasted seven days. During the first five it was relieved somewhat by cold applications, which were replaced by hot ones on the sixth, and continued for two days. After this, the pain occurred only occasionally. The pain in the neck and arms was not so constant, but when present was severe. Shampooing relieved it more than anything.

The severe pain prevented sleep at night. This was combated by morphia and atropia, $\frac{1}{8}$ grain of the former and $\frac{1}{200}$ of the latter to the dose.

For five or six weeks the left eye was drawn inward and upward, double vision resulting.

At no time during the illness did the temperature rise higher than 101° F.

The functions of the urinary organs were not interfered with at all. Menstruation was in progress at the time of the accident, but continued as though nothing unusual had happened.

Constipation was marked for a time, there being no movement of the bowels for five days after the accident. This was brought about by the use of enemas and small doses of gray powder. After this, the bowels acted regularly.

The treatment of the case consisted in combating the symptoms as they appeared; but it is very doubtful if any good was accomplished by the use of drugs, with the exception of the morphia, atropine and gray powder, although bromide of potassium, quinine and several other remedies were used.

The patient remained in bed two weeks, then sat up for a short time daily, until at the end of four weeks she was able to take a ride of thirteen miles in the cars to her home.

Complete recovery has taken place with the exception of the left eye; the vision of which is somewhat impaired.

The management of the case immediately after the accident was conducted by Mr. Paige, then an undergraduate, who was on the spot at the time.

REMARKS ON THE OPHTHALMOLOGICAL ASPECTS OF THE CASE. (BY DR. FRANK BULLER.)

There was a steady improvement in the visual acuteness for some two months after the accident, but no perceptible improvement has taken place since then. The patient suffered severe pain about the eye and left side of the head for about a week after the injury. There is nothing abnormal in the external appearance of the eyes nor any evidence of injury to the adjacent parts.

The conjunctiva, cornea, anterior chamber and iris appear just as in the other sound eye. The pupil is of medium size, but does not respond to light quite so promptly as that of the other eye. The existing visual defect prevents an accurate estimate of accommodation, but the ciliary muscle is certainly not inactive. Vision of right eye $= \frac{6}{VI}$, slightly better with + 0.5 c. ax. 90°. Left eye, vision $= \frac{20}{L}$, not improved by any glass. All the extrinsic muscles appear to do their work efficiently.

Two hours after free instillation of solution of homatropine, gr. viij ad ℥j, there is R. H. = 1 D., vision $= \frac{6}{VI}$ L. H. = 1.5 D.; vision $= \frac{6}{XV}$. Under ordinary circumstances there is binocular vision, but a vertical prism gives a lateral convergence = 18°, abduction = 3°, adduction = 42°, and ? right hyperphoria = 2°.

It will thus be seen that there is an insufficiency of the external recti which may be her normal condition, or, in view of the fact that there was no visual disability of either eye prior to the accident, it is more probable that the left external rectus had not fully recovered from the effects of the injury.

By facial illumination there is seen to be a considerable opacity at the posterior surface of the lens very like that of an ordinary posterior polar cataract, with this difference: the opacity is obviously, for the most part, situated in the lens substance, and does not, like the so-called posterior cataract, present a concave anterior surface.

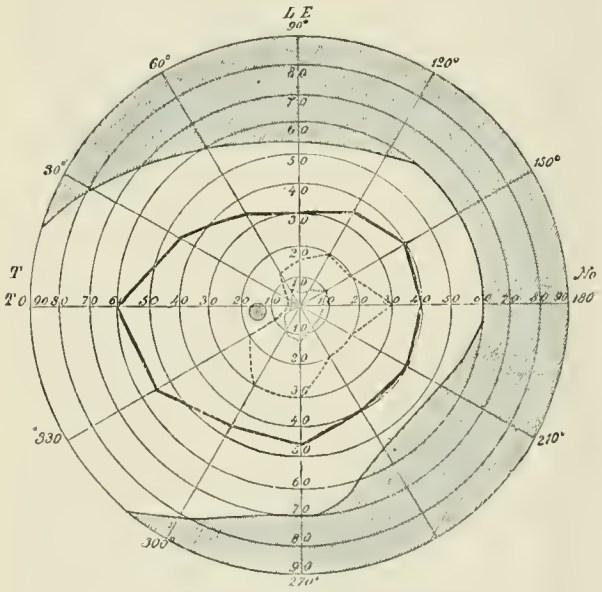
The opacity has a circular outline, but is not sharply defined, and beyond the principal opacity there are some nebulous cortical opacities extending further toward the posterior periphery. The vitreous humor contains a few floating particles so fine that they are seen with difficulty even with the aid of a + 6 D., ocular behind o. mirror. The optic nerve is very pale and its margins slightly blurred, but this may be partly due to the defective transparency of the lens. There is nothing else indicative of an optic neuritis, past or present.

In addition to the pallor of the nerve, there is a considerable diminution in the calibre of the retinal bloodvessels, with loss of the fine vessels on the papilla to about the same extent as may be observed in an ordinary case of moderately advanced simple atrophy. Several of the larger vessels, both veins and arteries, have whitish borders for some distance in the retina. Other than these there are no visible changes in the fundus oculi until we come to the extreme periphery, at and somewhat below the horizontal meridian. Here there is a broad patch of irregular choroidal pigmentation composed of ill-defined masses of dark pigment, but not so black as the pigmented deposits commonly seen in choroiditis. The anterior boundaries of the pigmented area extend beyond the ophthalmoscopic area, but about the centre of the patch there is an irregular break

about the size and shape of two of the papilla partly overlapping each other. This patch is itself partly covered with pigment, but is of a dull orange color. If due to atrophy of the choroid at this part, the atrophy is not sufficiently advanced to show the tendinous whiteness of the sclerotic. It would seem to be either a rupture of the choroid at this part or an imperfectly absorbed effusion of blood, or, what is more probable, both these conditions are present.

It will be seen from this description that the injury has resulted in damage to the external muscular apparatus, the crystalline lens, the choroid and, lastly, the optic nerve. No doubt the visual defect is chiefly due to the latter, for there is a very pronounced concentric limitation of the visual fluid, such as we might expect to find in partial atrophy of the optic nerve, but which could not have resulted from any of the other lesions mentioned.

The color sense, though impaired, is pretty uniformly restricted for all colors (see chart of field). It is not easy to explain how this has happened, since we have no knowledge of the ophthalmoscopic changes shortly after the injury.



The white area in the chart of the visual field represents the normal limits of the field of vision for white of one eye whilst the individual is steadily gazing at the central point.

The heavy black line in the chart represents the actual (much diminished) area of the patient's visual field for white. The interrupted and dotted lines are the areas for the colors red and green respectively. These are also much contracted—about in the same proportion as the field of vision for white, but less regularly so.

There might have been an effusion into the tissues of the orbit causing pressure on the optic nerve behind the eye; or an effusion of some kind into the sheath of the optic nerve, or an interstitial neuritis as a result of concussion of the nerve, and any one of these conditions might have resulted in the existing partial atrophy.

I have not been able to find in ophthalmic literature any case of injury to the eye from lightning, in which an ophthalmoscopic examination was made shortly after the injury, with the exception of Brudenell Carter's case (*St. George's Hospital Reports*, vol. v. p. 322), incorrectly credited to H. Power by T. Leber, as well as by de Wecker and Landolt. In this case such an examination was probably made, but there is no mention of ophthalmoscopic changes; moreover, the injury was not caused by direct contact of the electric discharge with the patient's body, and as the man recovered perfect vision a few days after the injury it is not at all likely that any visible intraocular lesions were present. Of the few cases that have been reported since the ophthalmoscope came into use, those presenting intraocular lesions were all actually struck by the lightning. In one (reported by T. Leber in Gräfe's *Arch. für Opth.*, Band xxviii.) the general disturbance, burning of the surface, shock and paralysis, were greater than in our case. In this instance, too, both eyes were seriously damaged. Nevertheless the ocular lesions in our case are remarkable both in their number and severity.

The injuries known to have been inflicted on the eyes of the few cases hitherto reported, may be summed up as follows: Paralysis of the muscular apparatus, including the muscles of accommodation, cataract, deep-seated changes in the ocular tunics, such as ruptures of the choroid, choroidal and retinal hemorrhages, detachment of the retina, paralysis of the optic nerve in the form of atrophy of the nerve. Four of these conditions were present or had existed in our case, and may fairly be attributed to the injury, since, as already stated, there was no known visual abnormality prior to the accident.

REMARKS ON THE GENERAL PHYSIOLOGICAL ASPECTS OF THE CASE. (BY DR. WESLEY MILLS.)

The history of the above case may be summarized as follows: The subject of the accident is a young woman, healthy, about twenty years of age, married, who was struck by lightning some six months since. The immediate effect was instant and prolonged loss of consciousness, complete cessation of respiration, and partial arrest of the circulation. The first sign of life appeared in from three to five minutes. The circulation remained in a very feeble condition for some time. When the respiratory system resumed its functions, breathing was greatly impeded by accumulations of saliva in the pharynx. Consciousness was restored in from one-half to three-quarters of an hour. There was paralysis of the muscles concerned in voice production and deglutition, and of the arms and probably other parts. After twelve hours, recovery of the higher cerebral functions was complete, with partial restoration of the ability to

swallow. Dysphagia persisted in some degree for more than two weeks.

There was severe pain in the head, chest and arms, most marked in the head, and lasting for several days.

An internal strabismus of the left eye lasted for five or six weeks, causing diplopia, then gradually passed away.

The catamenial flow, in progress at the date of the accident, continued as usual. The urinary functions were normal throughout, but constipation was pronounced for some days. The patient has completely recovered, with the exception of the vision of the left eye.

The treatment was, first, artificial respiration, with, later, the addition of warm fomentations to the chest; the subsequent symptoms were combated by morphia, atropia, gray powder and massage. The young woman's general health continues to be excellent.

It is not my intention, in these remarks, to enter into the subject of lightning shock in general, but to confine myself to a brief explanation of this particular case. Its scientific interest lies in the fact that it is an example of one of Nature's physiological experiments—or, shall we say, in consequence of its violent character and the nature of the results, pathological. At all events, it is a lesson in human physiology, as I conceive it; and human physiology proper is so meagre that every scrap should be gathered together and carefully preserved. In order to keep these remarks and the paper as a whole as brief as possible, I shall indicate my own views of the case without entering as fully as might be into the evidence on which they are based.

The unconsciousness was owing to the shock (abolition of function) of the cortical cells (and others) of the cerebrum, arising from the violent impulses reaching them chiefly along the nerves, and not by the direct entrance of the electric current into the brain—*i. e.*, the effect was physiological, not physical, chiefly. The cessation of respiration and (partially) of circulation is to be traced to a similar action on the nervous centres presiding over these functions. The heart was slowed, and its ventricular action rendered highly intermittent, owing to impulses through the vagi nerves. The condition of the circulation may be considered a reversion for the time to the reptilian type (see a paper on "Reversion," by the present writer, in the *Canada Medical and Surgical Journal* for April, 1888); but the vagus is a trophic nerve, and the heart, though being injured by the venous blood, is also being benefited by the impulses descending the vagi—hence, a preparation for recovery.

The artificial respiration and heat furnish oxygen and—what is essential to mammalian functional action of all kinds—a certain temperature. The mammal, in this case, is presently restored to its normal grade, and leaves the reptilian (cold-blooded) condition, in which it could exist for a brief period.

There are many indications to show that the cord did not suffer as much as the brain, which is explicable by the site of the original impact of the current (head). Hence the leg can shortly be drawn up—a revived reflex, probably. The menses are not interrupted. On the other hand, there is constipation not to be accounted for wholly by the inactivity in bed, but by the inhibitory influence of the brain over the cord, which latter Goltz has clearly proved to be alone essential for defecation. At first it is a shade surprising that the menses were not interrupted as the action of the alimentary tract evidently was (constipation); but when the length of the latter is remembered and its abundant nerve-supply—the extent of cord thus nervously connected, etc.—the apparent mystery clears up in part, at least.

The paralysis of the muscles of the larynx, pharynx, etc., is to be traced to the effect of the current on the nerves themselves or their centres in great part, rather than to its direct action on the muscular tissue, though the latter need not be wholly excluded. This view is borne out by the pain which followed the paralysis, and which is best referred to the molecular changes in the nerve-tissue causing increased resistance to the passage of impulses which emerge in consciousness as pain. Since there was complete and rapid recovery of all the mental powers, the injury was probably chiefly to the nerves or the nerve-endings. Was the difficulty in respiration in this case owing to the secretion of an excess of saliva, or to the normal quantity not being swallowed at all, or to both? Experiment has shown that in the lower mammals an increase of secretion may be induced in two ways: either by stimulation of the nerves of the salivary glands, or by section of the nerves, which is, of course, equivalent to paralysis. Usually, however, in the cat, etc., the secretion following section of the nerves ("paralytic secretion") does not set in for some hours. One powerful electrical stimulation of the chorda tympani nerve will cause, in the lower animals, a considerable flow of saliva, which lasts for some time after the current is withdrawn. It may be that there was an excessive secretion in our case, due to paralysis of the nerves presiding over the secretions of the glands; but, upon the whole, it seems safest to regard the effects as due to failure in deglutition, with a possible excess of secretion, the result of the stimulus of the nerves by the electric current.

The good results following the use of morphia and massage seem to be in harmony with the explanations advanced as to the cause of the symptoms.

Why were the injuries to the eye most lasting? The œdema may be explained, either by a local or central effect through the nerves. Taking into account the fact that the current impinged so near

the eye, it is likely that both factors enter into the result. As none of the nerve-endings, we have reason to believe, are so delicate, so readily injured as the retina, it is not difficult to understand why the intraocular effects should be so permanent or, in fact, should be progressive, or even multiplied in kind.

Would this patient have recovered without the assistance rendered just after the accident? Considering that respiration was suspended, that the circulation, even with artificial respiration, was so feeble that the temperature fell, that consciousness did not return for so long, it does not seem reasonable to believe in the possibility of spontaneous recovery. But the case does seem to teach, in the clearest way, the importance of using such means as those employed in this instance promptly and perseveringly.

THE POISONOUS EFFECTS OF PETROLEUM.

BY W. H. SHARP, M.D.,
OF VOLCANO, W. VA.

IN the number of THE MEDICAL NEWS of May 19th, the leading editorial is devoted to this subject, based on an article in *Virchow's Archiv* by Lewin.

For the past nineteen years I have lived and practised medicine in an oil town, surrounded by oil wells, and in daily contact with laborers connected with the oil industry, and I hope the following observations may prove of interest.

In considering the effects of petroleum it is necessary to know clearly which kind of oil is indicated, as there are different grades of natural oil which must have different effects as they are richer or poorer in the lighter products, as gasoline, benzene, naphtha and carbon oil. The heavier natural oils, of specific gravities ranging from 26° B. to 35° B., such as are produced in West Virginia at this point, in Pennsylvania at Franklin, and at a few other points, are very different in composition from the lighter petroleum oils which range from 35° B. to 50° B., such as are so largely produced in Pennsylvania and Ohio, and are used for refining for illuminating purposes. The former are almost devoid of the gasoline, naphtha and benzene found in the latter, and do not make a satisfactory carbon oil. Where this heavy oil is produced there is found less gas than accompanies the light oils.

Again, the odor of various oils differs greatly, the heavy oils being less odorous than the light oils; and light oils also differ greatly from each other, as, for example, the oils from western Pennsylvania and northwestern Ohio. There are also differences in color. Some of these light oils also are not as well suited for refining for illuminating as others, while well suited for use as fuel.

From a tank of freshly pumped heavy oil, such as is produced here, there is almost absolutely no gas; as the oil approaches in quality the light oils, the quantity of gas increases. These heavy oils up to 32° or 33° specific gravity B. are not inflammable; a lighted taper could be dropped into a tank full of such oils with no more result than if dropped into so much water. From a tank of oil from 40° to 50° B. there is constantly an escape of gas, most inflammable, and the greatest care is necessary as to lights, etc., about the tanks and wells.

The worker in these heavy natural oils runs no risk at any time from the inhalation of gas, even in the tank sheds where the oil is stored, and the engineers at the pumping-stations of the transportation companies are exposed to no dangers from inhalation of gas.

During my residence here there has not been a single accident of this kind; and I have known of but two or three instances in which men suffered from the effects of gas when cleaning out tanks in hot weather. In these cases they suffered from dizziness and headache, which effects were transitory. As much of the heavy oil is mixed with water when it comes from the wells, it is allowed to stand in tanks for some time to separate. The water is drawn off from these tanks from time to time, and has a peculiar, sweetish, sickening odor, which is very disagreeable.

In all the light oil districts serious accidents are quite frequent from the inhalation of gas. It is, I believe, the practice to have the receiving tanks at the wells closely housed with wooden sheds, at the roofs of which are ventilators for the escape of gas. This past spring, one of my neighbors, an oil man, who had gone to North Baltimore, Ohio, for work, was suffocated in one of these tank sheds while making a run of oil, viz., running the oil from the receiving tank to the transportation or pipe line company's tanks.[1] It is said that the men employed in this work by the transportation companies become somewhat accustomed to this gas and can then remain longer exposed to it before feeling its effects. Oil-well drillers have told me that the sense of suffocation comes on very suddenly. When the gas is very plenty around drilling wells and if there be any delay in getting pure air, suffocation ensues. In this section, even when drilling in light oil territory, there is little danger from this, as our derricks are seldom tightly housed, as is the practice in other regions.

During my residence here I have never met with or heard of a case of skin eruption or acne, such as Lewin describes. My opportunities for observation have been ample; for ten years I was the only medical man in this locality, and most of my practice

[1] During the past week I saw in a Cincinnati daily paper a notice of the suffocation of two workmen in a tank-shed at Findlay, Ohio.

was among those engaged in or depending upon the oil industry: oil-well drillers, engineers pumping the wells, gaugers and laborers engaged by the transportation companies, men engaged in preparing the heavy oils for market in refineries located here—but we had no refineries engaged in making illuminating oils; and I feel certain that if natural lubricating petroleum oils produce such a condition of the skin I would have seen or heard of cases. Nor have I seen them among those of our workers who handled the lighter oils.

Heavy lubricating oils applied locally are not irritating; they are as bland to the skin as the best petroleum jelly or ointment. They have had a well-deserved reputation as soothing applications to burns and wounds; the heavier the oil the better it is suited for this purpose. These oils do not irritate any inflamed surface, but relieve the pain as well as does the linimentum calcis or white lead dressing. The only disadvantages I have found in its use are that the cloths become stiff from drying, and the application is a dirty one, penetrating the bedding, etc., if applied freely. A light oil 40° to 50° gravity would probably prove irritating from the presence of benzene, etc.

Internally these heavy *natural* oils have been used in pulmonary troubles, viz., bronchitis and phthisis; persons taking them in doses of from 1 to 4 f℥ several times a day. I have never known or heard of any ill effects from their administration. Of their use in larger quantities I know of no instances. Lewin speaks of experiments made upon animals, which demonstrated the poisonous action of the heavy oils, but he does not designate what heavy oils. Most heavy oils made from the distillation of the *light* oils, or from the *tarry* residue known as "still bottoms," no more resemble natural lubricating oils than butterine from diseased and dead animals resembles the best gilt-edge butter from a crack Chester County, Pennsylvania, dairy.

He further speaks of the greater liability to acne of those who work in the heavy oils and residue at the refineries. Perhaps a closer investigation would show that this effect is not so much due to the oils as to the chemical agents used in refining oils for illuminating purposes. It is well known that the oil is treated at one stage with sulphuric acid, and later with caustic soda, to remove any of the acid left after the washing of the oils in the agitators. This I *suggest* as a point of inquiry for those who attend the workmen at large refineries.

Very different is the effect of "carbon oil" applied locally. In this section it is used as a counter-irritant in domestic medicine in cases in which prompt effect is desired. Cloths saturated with it and applied to the skin soon cause redness, inflammation and, if kept on long enough, the occurrence of a fine vesicular eruption; the vesicles are of the size of small pin-heads. I have never seen pustules from it; these vesicles dry up and the epidermis desquamates. As a counter-irritant it deserves the attention of the profession, as it is nearly always at hand; nearly as prompt as mustard, equally so as oil of turpentine, much more so than croton oil; more permanent in its effects than the first two, it stands midway between these and croton oil.

Internally I have known it to be given in doses of from a half to one fluidrachm in cases of spasmodic croup. I believe that it sometimes gives relief by vomiting; at other times by promoting secretion of mucus and relieving spasm; but of this use of it I only write from hearsay. A friend of mine, for years an inspector and tester of the various grades of oils produced here, tells me that one winter, being much exposed to bad weather and subject to attacks of acute bronchitis, he used natural oil of 29° B. gravity three times a day all winter in doses of one-half fluidounce, with decided benefit; that he daily handled oils, at times his clothes being saturated, his hands constantly bathed in it, that it never had any other effect except to keep the skin in a soft, healthy condition; that among the employés of his company he has never heard of or seen any cases of skin eruption such as I described to him. On one occasion, standing by a tank into which *light* oil was being pumped, he inhaled the *gas* for some time mixed with air. It produced a species of intoxication, so that he could hardly walk, which soon passed off when he left the immediate vicinity of the tank.

Both crude oils of *lighter* grades and refined (carbon) oil are poisonous to the inferior grade of insect life, also, if applied freely to vegetable life. When the soil is saturated with them, it is ruined for some time; but the gas is never concentrated enough in oil regions to affect vegetation.

I have made a careful search in the *American Journal of the Medical Sciences* since 1869, and in other journals in my collection, and find only two cases of poisoning by petroleum recorded, viz., in the April number of the *American Journal of the Medical Sciences* for 1873.

Case I.—A pint of "merchantable petroleum" (refined oil?) was taken with suicidal intent. But slight indications of intoxication ensued; only slight pain in region of stomach and but little febrile excitement. From entire surface exhaled a strong odor of petroleum, but breath was entirely free from it. On the urine a thick layer of petroleum floated, not as a secretion from the kidneys, but as a kind of mechanical filtration. For six days the smell of petroleum was given out from patient's skin. The urine was slightly alkaline, contained 0.1 per cent. of albumin and was rich in pus and epithelial scales. The reporter, Dr. J. Steininger, remarks that on the outskirts of Vienna petroleum is drunk by the common people in the same way and for a similar purpose as ardent spirits by others.

Case II.—(*Medical Record*, September, 26, 1885.) Dr. Duguet, of the Lariboisière, reports the case of a man, aged forty-eight years, who swallowed about one pint of ordinary petroleum of commerce with suicidal intent. He felt at once a strong sensation of oppression along the

œsophagus and at the stomach, with a sense of humming, and was extremely agitated. He exhaled a powerful odor of petroleum, and vomiting being excited by ipecac. with large quantities of milk, a great deal of petroleum floated on the ejections, as on operations from the bowels following enemata. The urine was saved. That voided before administration of the emetic contained a floating layer of petroleum one inch thick; next day the amount floating on urine was about five drachms; on second day one drachm; then gradually ceased. Some albumin was present, but disappeared with the petroleum. During the first four days the petroleum prevented urine from undergoing decomposition for ten days.

From these two cases petroleum would not seem to be very poisonous, and to be chiefly eliminated by the skin and kidneys, especially the latter, unchanged by transudation.

That it is the lighter oils in the crude petroleum which produce the intoxicating effects, and that the acne seen in workmen is due to something used in the process of refining are highly probable; certainly they do not arise from contact with the natural oils of the heavier gravities, viz., 26° B. to 35° B.

THE GENERAL AND LOCAL EFFECTS OF PARAFFIN OIL UPON THOSE WORKING IN IT.

BY JOHN K. MITCHELL, M.D,
ATTENDING PHYSICIAN TO ST. MARY'S HOSPITAL, PHILADELPHIA.

THE diseases incident to various trades and occupations have not received a great share of the attention of physicians, with the exception of certain neuroses, which have been very thoroughly studied. My own notice was first called to the subject of this paper when serving as resident physician to the Episcopal Hospital of this city, some five years ago. In the dispensary at that time I had the opportunity of seeing several cases of eruptions caused by kerosene, or the oils refined from it. Unfortunately, I was ignorant of their interest and novelty, and in the hurry of a very crowded service kept no note of them beyond the mere diagnosis in the dispensary book. My recollection is that none of them was so bad as the cases which I have recently studied at the works of the Atlantic Oil Refinery. I noted them merely as "general furunculosis," and they were treated, as skin diseases are apt to be in general out-service, with arsenic, and by directions to the patient to "wash." They did fairly well, and slowly recovered. Afterward, when house physician, I saw a large number of cases, in the charge of Dr. Morris J. Lewis, of a trouble which we believed to be caused by the handling, by unaccustomed men, of refined kerosine oil.

The subjects were all sailors, engaged in the loading of oil in barrels on ships lying at Point Breeze. The men were seized, always suddenly, and always after some days of the labor, with cramp-like pains in the stomach and intestines, together with severe constricting pain about the lower part of the chest, with obstinate, slight diarrhœa, with nausea and, occasionally, with some vomiting. After attempting to trace the disease to the influence of the river water, and excluding that, and finding that they were lodged much as usual in their hard-working calling, and living in an accustomed way, with the exception that, owing to the harbor rules against lights on board vessels loading oil, they were obliged to eat, for the most part, cold food. But this is by no means unusual at sea, and we were finally forced to agree with the men, who themselves attributed their difficulties to the vapors from the oil. The cases yielded to simple treatment.

Within the last few weeks the subject of skin trouble from oil was again suggested to me by a talk with Mr. Livingston, Superintendent of the Atlantic Oil Refinery at Point Breeze. The first case which I saw from this cause has already been shown at the College of Physicians.

My notes of this man's history and condition are like those of all the others I have seen, differing only in degree. I will give them in full, commenting afterward on the causes and peculiarities.

J. J., aged thirty-nine years, German. A middle-sized, strongly made man, with a good family and personal history. He has worked three years in the paraffin department of the oil refinery, at first out of doors, handling the products, but not much in direct contact with them. During the second year he had a slight eruption of comedones and boils, which soon disappeared. In the autumn of 1887, he was put at work inside the press-rooms. In October, he had some boils on his arms; soon after, they broke out on his legs; for a time they varied in severity, but in January and February of the present year, they became so painful and troublesome that he stopped his work on March 6th.

On March 8th, I made a careful examination. The appearance of the man's face was not peculiar except that there were two or three parallel rows of largish comedones upon his forehead. On stripping him and examining his trunk, similar comedones were found distributed over his shoulders, chest, belly, arms and legs, together with numerous rounded, elevated, angry swellings on a red, inflamed base, varying in size from a small pimple one-eighth of an inch in diameter to a huge boil at the point of suppuration, and two or two and one-half inches across. Some of them were simply red swellings, others presented evidence of containing pus. The arm, from about two inches above the elbow anteriorly to the wrist, was almost covered with them, and both the anterior and posterior surfaces of the thighs, from above their middle to the knee, showed scarcely a square inch of healthy skin. Below the tubercle of the tibia the legs showed nothing wrong.

A closer study of the surface with a magnifying glass showed that the smaller swellings bore a hair about the middle of them, and this usually sprang out of or just along side of the central black spot of

the comedo. It was evident, both here and in the other cases, that the comedo was the original lesion. The distribution of these was extraordinary; not only were they seated on the face, in the interscapular space and upon the chest, in all which situations they may be commonly found in persons who suffer from this form of skin trouble, but their presence was universal. Rows of them ran across the belly, particularly just above the umbilicus and around the waist; they were even crowded together on the backs of the hands. The recent ones were like ordinary comedones, simple black spots. The next stage showed these spots a little larger and behind them tiny swellings under the skin; in the third stage the spots were distinctly depressed a little, or perhaps it would be more accurate to say that the edges of the skin surrounding them were well elevated and slightly red. They then continued to swell and grow more inflamed, until the inflammation had pushed up the whole swelling, and in place of the comedo there was a round red tumor, the color shading off into the normal about it. The swelling itself was hard, the tissue around thickened and dense, and the inflammation seemed to extend deeply. Apparently some of these remained in this state; others grew larger and larger, or several ran together until their size was, as I have said, in some instances, more than two inches in diameter. A close examination showed upon the surface of all of them one or more of the black spots about which the inflammation had begun. The whole of the front of the left thigh was occupied by five or six such tumors. The formation of pus in them appeared slow, for, on incising one of half an inch across, a single drop of pus was all that it contained, quite deep down. The microscope revealed no unusual character in this pus, except that much sebaceous matter was mixed with it. A comedo removed entire by careful picking out with a needle, was found, with a powerful glass, to present only the ordinary appearance of such cysts, except that the dark-colored matter which forms the top seemed to line completely the little oval sac on all sides, as though secretion of it had taken place from within. On cutting into it a microscopic study discovered nothing save sebaceous débris and this unorganized dark pigment. The result of numerous examinations of pus and the contents of these cysts was the same in every case, with one exception, which I shall mention later.

The patient stated that he had little pain, except that the swelling made his movements very stiff, and exertion stretched the skin so as to hurt him. The boils, he said, he opened himself when he thought they had "come to a head," and that, before they had become so numerous, this had relieved him greatly each time. His functions were in perfect order, and his appetite good. His skin had a very greasy feeling, although he had washed thoroughly just before coming to visit me. I may add here, that after the first baths which he took during his stay at the German Hospital, the surface of the water in the tub was noticed to be covered with floating oil.

I examined his blood, but found the corpuscles perfect in size and shape, and the hæmoglobin 59 per cent.

I am indebted to the kindness of Dr. George A. Bodamer for the following notes of the foregoing case, while under his charge in the German Hospital

"During treatment in hospital new furuncles made their appearance and old ones relapsed, very often to the extent of formation of abscesses, which were opened and considerable pus eliminated. From this condition a rise of temperature occurred, seldom, however, above 102°, and ranging between this and normal. The soda baths seemed to give him great relief and cleanse away the fatty matters. After such a bath, to rub himself with a coarse towel, would dislodge, to a surprising extent, the comedones. The furuncles which relapsed and formed abscesses were mostly on the upper parts of the legs and arms. Another symptom of which he complained was intense pain at night, sometimes to an extent requiring morphia."

I have since seen this patient, who has almost entirely recovered.

As I have said, this case presents the features of "paraffin eruption" in a typical manner. Before speaking of the variations which I found in the details of some other cases, I will describe briefly the process of paraffin making, in which all my patients were working. After several distillations for removing oil of different specific gravities from the crude petroleum, there remains a heavy tarry residuum, by a new distillation of which paraffin oils are distilled over, and pure carbon is left in the stills. The paraffin oil is treated in huge tanks, with sulphuric acid to destroy any organic matter which may be present, then with soda to neutralize the acid, and then with pressure, hot in one, cold in another chamber, the latter kept artificially cooled by brine which has been chilled by an ammoniacal process. The men in the room in which cold pressure is applied to the paraffin wax are those who suffer worst and most frequently from the eruption. There are several probable reasons for this. I was told by the superintendent that new men were generally set to work here first. The work consists in the carriage of the paraffin, which is about the consistency of stiff vaseline, from the receptacles where it has been cooled, to presses into which it is shovelled, and there squeezed to remove the oil.

The presses are arranged like cider-mill presses, and the packing involves much handling of the substance. The men were all working with their sleeves above the elbow, their trousers tightly tied below the knee, and loose gaiters of cloth or bagging strapped about the calf. The warm room was cleaner and much better ventilated, and although the process is similar, there is less direct contact with the wax.

In these two rooms I saw a number of cases. I shall only go into the details of one or two. It

appears from the testimony of the workmen, as well as from that of the superintendent, that, while most men are afflicted in from three to six weeks after going to work, some men never suffer at all. I saw one laborer who had been six years in this department, and never had had any trouble; but except the one already described, the worst eruption which I studied was in an Austrian workman who had been six months in the paraffin rooms before he had any trouble. Two months after the eruption appeared, slight improvement began, and it was just at this time that I saw him. In him the boils were chiefly on the arms and shoulders. The legs were less affected. I examined the urine of this patient very carefully, but could find nothing abnormal. In studying his blood, I did discover a curious but isolated fact. There was a distinct difference in the sizes and shapes of the corpuscles. The red corpuscles were cup-shaped, balloon-shaped, ovoid or crenated, and the sizes varied a good deal.

In three examinations of this man's blood I noticed this condition of poikilocytosis growing less in each. In the last examination the blood seemed to have returned to a natural state. The blood was studied within a minute of its withdrawal, so as to be sure of its freshness. The patient's general health was excellent.

In one case, in which the skin lesions were few, I found what I took to be fat crystals in the pus removed from a boil, and these were present in all of several slides made from it. I studied the blood, pus and urine in several other cases without noting anything unusual.

Anatomically, it is interesting to observe the situation of the boils. I believe that every one of them began in a hair-follicle, or at least this was true of every one of which I was able to note the commencement. About this seat the inflammation centred. If the hair-follicles and the sweat glands be as intimately connected as is sometimes asserted, this could hardly be otherwise. Again, it is at least curious that in no case were any boils observed upon the head, though, of course, this situation is usually well protected by a hat from contact with the oil; still, if it penetrates through several thicknesses of clothing to the limbs, why should it not make its way past so slight a barrier as a light cloth or straw hat?

To these details is to be added the fact that the general health of the workmen in paraffin seemed to be very good; those who had never had the eruption and those who had convalesced from it had clean skins and every sign of good condition.

Men suffering from the boils appear not to be affected beyond the local irritation unless it grows very severe. The paraffin seems to have no other than a local action; new men are attacked, as I have said, usually within a few weeks, sometimes not for months. In ordinary cases the irritated regions are the flexor surfaces of the arms, the front of the belly above the waist and the thighs; rarely the lower leg. The Superintendent of the Atlantic Company told me that his long experience in the oil regions and in Philadelphia had made him sure that friction was a factor. With this I incline to agree. The rolled sleeve rubs into the hollow of the elbow and below it, and here are the most spots on the arms. The trousers are strapped about the waist, and in several men I found a row or two of pimples and comedones extending around the body at this height when the abdomen was otherwise clear. The trousers' legs are fastened below the knee, and this makes them rub the knee and draw tight over the thigh. The clothes, of course, are soaked with the oil, and it is rubbed persistently into the skin by the friction of the moving garments.

I am a little at a loss to account for the cold-room men suffering more than those in the warm room. The latter are rather less in actual contact with the oil, and perhaps the warmth of the room renders the oil more fluid, and promotes a sweat-secretion which helps to carry it off. New men require some suffering to teach them the necessity of washing both themselves and their working clothes, and it is in the cold-room, as above mentioned, that new men commonly begin.

The workers in benzene suffer, I am told, in a similar way, but I have not been able to see any cases; and in the oil regions, pump-men, who are liable to be splashed by the crude oil, have the eruption badly; but here the crude oil is handled entirely by pipe-lines, so that the laborers have no direct contact with it.

I have not seen or heard of any cases such as Joseph Bell describes, in which paraffin had caused an epithelioma of the scrotum (*Edinburgh Medical Journal*, xxii. part i. p. 135).

I believe the only case hitherto reported in this country is one described in a brief note by Professor Harrison Allen in the *American Journal of the Medical Sciences* (1882, N. S., xliii. p. 92), in which kerosene oil was the cause.

I have recommended to the Superintendent of the Refining Company, who requested me to suggest a method of prophylaxis, that he should try to get the men to use a weak soda solution for their washing after work.

Note.—No reference has been made in this article to a very interesting paper by Dr. L. Lewin, "Ueber allegemeine und Hautvergiftung durch Petroleum," in *Virchow's Archiv*, cxii. H. 1. Dr. Lewin studied several of his cases at the Atlantic Oil Refinery, and gives an excellent lithograph of the lesions in one. The present paper, however, was completed before the appearance of Dr. Lewin's, and I have left it as originally written.

A CASE OF ABSCESS OF THE LIVER, WITHOUT THE USUAL DIAGNOSTIC SYMPTOMS.

By JOHN L. DAWSON, Jr., M.D.,
of Charleston, S. C.

On March 6, 1888, I was summoned to H. S., a mulatto, male, aged thirty-five. During the early morning of the day previous he had been feeling badly, but had no prominent symptoms, merely a general malaise. After a restless night, he was suddenly seized with a severe chill, lasting for twenty minutes.

He was seen for the first time about two hours after this rigor, and found with a full, bounding pulse, moist skin and a temperature of 102° F. He had a history of having had an attack of malarial fever nine years before, and having recently spent several nights on the confines of the city in pursuance of his avocation, that of a policeman. The presumption was that we had to deal with an acute attack of miasmatic poisoning. He was given a mercurial purgative and ten grains of sulphate of quinine at bed-time, to be followed by five grains of quinine in the morning.

The next morning his temperature was normal, and his skin was secreting actively. His bowels had been evacuated and all of his functions were acting well. Toward evening he had another chill, followed by a rise of temperature, and again his temperature fell toward morning. This state kept up for three or four days, when he missed his evening chill, but the rise of temperature remained; falling from 101½° or 102° in the evening to 99° or 99½° in the morning. His sweats became more profuse. Quinine had no effect whatsoever; it was increased until at the tenth day he had taken grs. x morning, noon and night. This failed to produce any sign of cinchonism. Antipyrin and acetanilid were both tried at the rise of the fever toward evening, but abandoned on account of the production of more intense sweating. Every function was acting normally. The urine, though high colored and somewhat scanty, gave no evidence of disease when subjected to chemical tests. The bowels, naturally inclined to costiveness, acted every second or third day, and were normal in every respect. Percussion and auscultation of the thoracic region gave no signs whatsoever of pulmonic or cardiac lesion. There was no abdominal pain, no tympanites, no iliac gurgling and no rose spots.

We were at a loss to account for this daily exacerbation of temperature unaccompanied by any symptoms of its cause, until the end of the second week, when the rigors suddenly returned. They were very intense and of long duration; the temperature rose to 104° in the evening, with a morning decline to 100° or 101°. The patient was becoming exhausted, rapidly losing flesh and spirits. The actions at the end of the second week gave the first symptoms. The bowels, after having been confined for two days, were opened by a simple laxative, and the feces were white or of a very light clay-color, of a soft consistency and offensive odor, having very much the appearance of mixed mortar. Evidently the liver had ceased to act That organ was again examined and its outline carefully made. There was no enlargement and no tenderness on pressure. The patient had not a single ache or pain anywhere, slept well and digested his nutriment easily. These rigors, light colored stools and exacerbations of temperature continued for six weeks, the patient gradually losing flesh and strength, until April 18th, when he sank into a comatose condition with muttering delirium and all the evidences of approaching dissolution.

The diagnosis of the case was an exceedingly difficult one, there being no collection of symptoms to guide us. The clay-colored stools, the constant pyrexia, the profuse sweats and the occasional severe rigors pointed to septicæmia. The antecedent history gave no evidence of importance, but we suspected abscess of the liver. Abscess or a collection of pent-up pus would account for the sepsis, and the absence of bile in the excretion showed a derangement of the liver. Upon these two slight signs we made the diagnosis of hepatic abscess. Three days before the patient's death the liver was carefully examined in hopes of finding some point of swelling or fluctuation, and an aspirator was taken to the bedside to attempt a confirmation of the diagnosis, but failing to find the slightest physical sign my consultants agreed that the attempt was not warrantable.

Autopsy.—On April 26th, six hours after death, the cadaver was opened and the abdominal contents examined. The liver presented an abscess of the right lobe containing about four ounces of thick, grumous, yellow pus. The abscess was situated about half an inch to the right of the broad ligament, on the upper surface of the right lobe against the diaphragm. The rest of the organ was normal. The gall-bladder contained some bile but was not distended. The stomach and intestines were normal, but shrunken and empty. Kidneys normal. Lungs, heart and brain not examined.

Remarks.—The interesting features of this case were the total lack of pain in the hypochondriac region; the fact that an abscess of such a size could have existed without giving rise to any symptoms save those of sepsis; and an inability to evacuate the pus had the diagnosis been indisputable. There was no needle in an ordinary aspirating case long enough to have entered the abscess cavity by external puncture.

Although there was a total absence of bile in the feces there was bile found in the gall-bladder. The skin and conjunctivæ were not in the least tinged with biliary coloring matter, and at no time during the disease was there evidence of icterus. The skin was somewhat waxy in appearance, but this was not taken into consideration on account of the natural color of patient, who was a mulatto of an albino cast.

HEBRA'S BATH CURE IN PHAGEDENA.

BY ALLEN J. SMITH, M.D.,
ASSISTANT DEMONSTRATOR OF PATHOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

THE following case, illustrative of the beneficial effects of the prolonged bath, suggested by Hebra in certain dermal affections, occurred under my care, as interne in the venereal wards of the Philadelphia Hospital, in 1886, and the prompt relief in a case of such grave prognosis, has seemed to warrant its being recorded.

R. M., about twenty-five years of age, a concert-hall singer and performer, had applied in February of the year for treatment of a chancroid of the prepuce contracted several weeks previously. He was a well-built young fellow, but of rather poor general health, due to his loose and irregular mode of life. He denied syphilis, but had had gonorrhœa several times. The foreskin, which was large and œdematous, was removed by the house surgeon on account of the discomfort and trouble occasioned in urination and from the retained secretions. For the first few days, no untoward symptoms were manifested; but presently the wound took on the phagedenic type, and slowly advanced, in spite of every treatment, to the destruction of the penis. Several enlarged glands in both groins shortly suppurated, were opened, and, failing to heal, were also attacked by the process. In August, when he came under my care, he had been under more or less continuous treatment by the internal exhibition of the potassio-tartrate of iron, with external dressings of the same, had had local applications of fuming nitric acid and other similar agents, had had specific remedies—all to no purpose; he was also receiving special dietetic treatment. The local condition and his general health, however, were both steadily proceeding to the worst; and a consultation of the visiting staff had decided against amputation of the penis, as a *dernier ressort*, as without hope on account of the advanced stage of the disease. The larger portion of the glans had entirely disappeared; the process had extended back over the penis, which was of the average size, until within less than an inch from the abdominal wall; almost all the skin was removed, and the spongy bodies were markedly involved. The superficial structures of the lower iliac regions were invaded to a marked degree, and the whole case was regarded with grave doubt as to the final outcome.

With permission of the surgeon in charge, Dr. A. W. Ransley, the man was at once ordered to be placed in a sitz-bath every day for as long a time as he could remain, the water to be kept at the body temperature. After removal from the tub the sores were dressed with iodoform, and the patient kept in the recumbent position, and the diet carefully regulated. The first day, he remained in the tub somewhat more than two hours, and the second, about four hours. On the third day, he remained in the water about five hours, and by this time the phagedenic process, which had been of late rapidly advancing, was visibly checked; and, too, the pain attending the sores was so much lessened that the morphia and camphor, which he had been regularly receiving every day, were discontinued. After the third day, rapid and astonishing improvement took place in the local condition, as well as in the general health, of the patient; and after this time, he spent about eight hours daily in the bath, and in a short time was permitted to walk about when not in the tub. Within the month, he was brought before the class as practically cured, but several small and deep portions of the sores remained open some weeks longer, and eventually required to be touched with a caustic before they finally became cicatrized. The vast bulk of the cure, however, was accomplished within four weeks from the commencement of treatment.

It was feared that the hard cicatricial tissue which covered the penis would react disadvantageously in case of erection; but compensation from the healthy epiderm about the genitals took place gradually, and, when last under observation, several months ago, the penis, while disfigured, was not a source of inconvenience. Several small perforations into the urethra, near the end of the glans, have persisted, causing a sort of water-pot stream in urinating; not, however, incommoding the man to the extent to have him consent to a secondary operation.

No debilitating effects were experienced from the prolonged immersion during the treatment, and not the slightest untoward symptom required attention. That the influence of the bath is only local goes without saying, and the marked improvement in the man's general condition could not have happened except from its beneficial result upon the sores primarily. A trial of the bath upon a general syphilitic, with large, deep tubercular ulcers upon the thighs, was followed by no result whatever; although, later on, these yielded to specific treatment combined with local applications of nitrate of silver and the écraseur.

223 S. SEVENTEENTH ST., PHILADELPHIA.

MEDICAL PROGRESS.

The Treatment of Diabetes Mellitus. — EICHHORST (*Schweiz. Corr. Bl.*, No. 13) cautions against the sudden institution of an absolute meat diet, as this carries with it certain dangers. Saccharin is useful in the dietetic treatment of diabetes, but must not be given indiscriminately, lest an unpleasant, sweetish after-taste remain or nausea or disgust arise. The author considers saccharin-cocoa a useful beverage, notwithstanding that it contains a not inconsiderable quantity of starch.

Little is to be expected from medicinal treatment, though Eichhorst saw a case treated with arsenic and another with opium, in which the sugar disappeared from the urine. Of treatment at the springs, the author gives Carlsbad the preference. The majority of patients return from Carlsbad with urine free from sugar. The cure is, however, not permanent. Antipyrin is not available in diabetes mellitus; in a case of diabetes insipidus, on the contrary, in which three gallons and a

half of urine were daily passed, the amount was permanently reduced to the normal upon the exhibition of seventy-five grains of antipyrin daily.—*München. medizin. Wochenschr.*, July 10, 1888.

The Treatment of Tension as met with in Surgical Practice.—In a lecture delivered before the Royal College of Surgeons of England, Mr. Thomas Bryant summarized his views as follows:

1. The pain associated with every form of inflammation of the bone or of the peritoneal covering is due to tension, and the severity of the pain is a fair measure of its intensity.

2. In acute inflammation of the bone or its periosteum, tension is the chief cause of necrosis; and in the subacute and chronic forms, it is a potent cause of their chronicity, as well as of the destructive changes which, as a rule, follow.

3. The relief of tension, wherever met with, when the result of inflammation, is an important principle of practice which should be always followed. In bone, the principle is most imperative, on account of the difficulties under which natural processes act in that direction, by reason of the absence of elasticity or yielding in bone, and by reason of anatomical arrangements of its vessels which favor blood stasis.

4. To relieve tension in the softer tissues of the body, the local application of leeches, local or general venesection, acupuncture, aspiration, punctures and incisions may be requisite; whereas, to carry out the same practice in endostitis or periostitis, subcutaneous or open incisions down to the bone, and the drilling, trephining or laying open of bone by a saw, may be required, the choice of method having to be determined by the requirements of the individual case.

5. In the early or hyperemic stage of inflammation of bone, before destructive changes have taken place, experience seems clearly to indicate that the relief of tension—as indicated by a dull, aching pain, etc.—by means of drilling or trephining into bone, may arrest the progress of the disease, and help toward a cure by resolution; whereas, in the exceptional cases in which this good result does not take place, suffering is saved and destructive changes are limited.

6. In articular ostitis, of every kind and variety and in every stage, this mode of treatment cannot be too strongly advocated, as tending toward the prevention of joint disease.

7. In acute or chronic abscess of bone, diaphyseal or epiphyseal, the abscess cavity must be opened as any other of the soft parts, drained and dressed in the most appropriate way—the principles of treatment being the same in hard or soft tissue, although they are modified by the anatomical conditions of the parts.—*Medical Press*, July 11, 1888.

Aphasia with Disturbance of the Musical Faculty.—Kast, of Freiburg (Verslg. d. Südw.-deutsch. Neurologen u. Psychiater), has reported a case in which, in consequence of a traumatic aphasia, inability to sing manifested itself, while the patient remained capable of discriminating the finest intervals and of detecting errors purposely made by the musician. When the patient attempted to sing an air, the rhythm was precise, but he could produce no melody. The speaker also had under treatment a violinist suffering with cerebral syphilitic aphasia, but with unclouded intelligence. In this case, too, the musical disturbance is of a purely motor nature. The patient is unable to make the necessary movements of execution, but is cognizant of his errors, and accurately detects those made by others. By industrious exercise he has made good progress in singing, but in violin playing, on the contrary, there has not been the slightest improvement.—*Wiener medizin. Presse*, July 1, 1888.

Resection of Intestine for Intussusception.—Dr. Vasilieff describes in the *Chirurg. Vestnik* the case of a convict, aged twenty-five, who was seized with abdominal pain and vomiting. Laparotomy was performed in the prison hospital at Warsaw. A swelling was soon detected in the right hypogastrium, when the hand of the operator was passed into the abdominal cavity. This swelling was drawn forward and found to be an advanced invagination of the ileum into the colon; there was a very long meso-cæcum. The invaginated small intestine could not be reduced; so an elastic ligature was tied around the gut in two places, and the ileum and mesentery were divided. Then the invaginated ileum was readily extricated and about seventeen inches were resected. The abdominal cavity was well washed out with a solution of sublimate, and the cut ends of the gut were fixed by sutures to the abdominal wound. Much gas and fecal material escaped when the ligatures were untied. At the third week, the patient had an attack of hypostatic pneumonia, but recovered. At the sixth week, Dr. Vasilieff did an operation for the cure of the artificial anus. About six inches more of the intestine were resected, and the cut ends united by Czerny's suture. On the third day a motion was passed, but on the fifth, feces were found in the dressings. Three attempts to close the fecal fistula by suture failed. Digital exploration showed that a spur or valve was beginning to form. To this spur a pressure-forceps was applied; it fell off on the third day. Ultimately the fistula was completely cured.—*British Medical Journal*, July 21, 1888.

Secondary Fever after Scarlatina.—Gumprecht, carefully excluding complications and extraneous conditions, in a study of 228 cases of scarlatina, at the General Hospital at Friedrichshain, found a secondary fever in 13 cases, or 5.7 per cent. of all. He thus sums up the results of his study: 1. In a small proportion of cases of scarlatina there follows a distinct secondary fever, without detectable complication. 2. This fever immediately succeeds the scarlatina, or sets in some days after the temperature has reached the normal, and lasts of itself a few days to almost two weeks. It usually disappears with improvement in the general condition, and in the vast majority of cases terminates in recovery. Death results from exhaustion or from the occurrence of grave secondary complications, to which the secondary fever seems to predispose. 3. The fever is probably a distinct form of secondary infection and is related to the streptococcus of scarlet fever. It is also probable that the streptococcus finds entrance through the inflamed tonsils. 4. The biological activity of the streptococcus seems to exhaust itself in the pyrogenic action as a visible expression. 5. For the practitioner the recognition of the secondary fever demonstrates that the continuance of fever does not necessarily make the prog-

nosis of scarlatina the worse, but that he must be prepared for severe complications occurring late.—*Deutsche medicin. Wochenschr.*, July 5, 1888.

For Eczema of the Anus and Genitals.—LUSTGARTEN recommends the following ointment in this painful affection :

R.—Oleate of cocaine . . . ½ to 1 part.
Olive oil . . . . . 2 parts.
Lanolin . . . . . 10 parts.—M.

Apply this ointment twice a day to the affected part. —*Gazette de Gynécologie*, July 15, 1888.

The Diagnosis and Treatment of Ulcer of the Stomach.—PROF. GERHARDT, at the commencement of his address on this subject before the Berlin Medical Society, observed that catarrh of the stomach, which formerly took the place of a diagnosis, was now a rare disease. Cardialgia, that had formerly, as a functional disease, occupied a very lonely position, had now got nervous dyspepsia and incontinence of the pylorus as associates. In place of the anatomical conception of a disease, the physiologist had rather come to the front. It was known that ulcers of the stomach heal very quickly, and it had been repeatedly shown that portions of mucous membrane could be removed from the human stomach without any permanent ill effects. In gastric ulcer we had not alone to deal with a necrotic process, arising from auto-digestion, but with a chronic ulcer, and in this disposition to chronicity lay a distinguishing factor as opposed to the loss of substance. A third factor was mostly to be sought in the action and characters of the gastric juices. Only in a few cases, in old callous gastric ulcers, for example, could the reason for the permanency be found in the structure of the tissues.

In the majority of cases it was some change in contents of the stomach that acted on its walls and gave origin to the continuance of the ulcer. Injuries from medicines, such as tartarized antimony and salicylic acid, were to be taken into account, forms of fungi, as also a certain hyperacidity of the contents of the stomach. A great danger to the patient lay in the bleeding to which the ulcers gave rise. In his Würzburg statistics, bleeding took place in 47 per cent. of the cases. Lebert in 104 cases had only remarked its absence in 22. The hemorrhage did not always take place from the vessels of the stomach itself, but from those of neighboring organs, for old ulcers often had their floor in other organs, most frequently in the pancreas, next in the left lobe of the liver, more rarely in the spleen. Vicarious menstruation could take place even through a healthy gastric mucous membrane, but such an occurrence was extremely rare. The absence of any palpable tumor had been adduced as an important negative symptom of gastric ulcer; he did not place much reliance on that. According to his views, four kinds of tumors could be present with gastric ulcer: old ulcers with callous margins, which could often be felt through the abdominal walls, or through the left lobe of the liver; another kind belonged to the pylorus, and was a tumor of indirect origin, from extraordinary thickening of the pyloric musculature; circumscribed exudation around perforations gave rise to a third and very rare form; a fourth kind was caused by the crowding of neighboring organs into a large gastric ulcer. In view of all this, the examination of the contents of the stomach was very important.

As regarded the much discussed hydrochloric acid question, he had lately, in twenty-four cases of circular ulcer, found the reaction normal in seventeen cases, but not in seven. Three of these had had hematemesis, two were strikingly anemic individuals, in whom the absence of acid reaction was explainable. The hydrochloric acid was occasionally considerably diminished after serious loss of blood. The observations of others agreed with this, and it must be taken as an undoubted fact, that, in some cases of gastric ulcer, the increase of the hydrochloric acid, which had been generally set up as an absolutely certain sign of the existence of a gastric ulcer, might be wanting.

The normal amount of hydrochloric acid in the digesting stomach varied greatly—between 0.05 and 0.4 per cent. The hydrochloric acid reaction was generally absent in the carcinomata, but exceptions were met with. In sixteen cases of carcinoma observed by him the acid reaction was present in two. The duration of the ulcer was sometimes as long as twenty-five to thirty years, with intervals of good health intervening, so that the patient was looked upon as cured. If a disease of the stomach had lasted three years without the formation of a tumor, we were justified in assuming the probability of a gastric ulcer. The seat was generally to be determined by the situation of the pain, which was rarely absent in fresh ulcers. The presence of pain was the more valuable for diagnosis when it was not near the xyphoid cartilage, but at a distance away, when it coincided with tenderness on pressure, came on at a fixed time after food and was worse in certain portions of the body. With contraction of the stomach it was generally at the cardiac end, with dilatation at the pyloric. With tenderness on pressure and the presence of a tumor, one would conclude the case to be one of ulcer of the anterior wall of the stomach, with a frequent bleeding one in the posterior wall, because tumors in front were more inclined to perforation, those behind more to hemorrhage. When a patient abstained from food, from pain in the stomach, and became thin and reduced in consequence, the disease was more probably ulcer, hardly carcinoma, rarely nervous dyspepsia. In the case of recent ulcer great loss of flesh was rare, but emaciation was often observed in old cases; weighing of patients was of great importance from a diagnostic point of view.

As regards treatment, diet took the first place, and, besides this, regard to the etiological condition and the character of the contents of the stomach were of importance. It had been proposed to feed the patient per rectum, but in many cases this was not practicable, as frequently there was a persistent hypersecretion of gastric acid. In recent cases, milk diet often sufficed, but in old ulcers, in which structural changes had taken place, milk was frequently not borne at all. Peptones he could not praise. Even if they could be taken, they caused a secretion of gastric juices, as Schiff had shown. In cases of profuse hematemesis and perforation, on the other hand, they were very serviceable per rectum. Peptones were, therefore, very suitable for cases in which alimentation by the stomach could not be carried out. In many cases a continuous secretion of gastic juice was present; this was diverted from the ulcer by meat or egg diet. Most physicians, therefore, recommend a diet mainly animal,

meat, milk or eggs. In cases of stenosis of the pylorus in which a tendency to lactic and butyric acid fermentations was present, one was compelled to give a diet consisting principally of flesh meat and to avoid the hydrocarbons as much as possible.

As regarded drugs, he did not think the use of morphia justified except in extreme cases, as under its use the patient was more easily inclined to indulge in errors of diet. In cases of doubtful diagnosis, hydrochloric acid was much employed; in cases of anemia, it was advisable in exceptional cases. He had obtained good results with perchloride of iron. Alkalies had not obtained much repute in the treatment of circular ulcer. Bicarbonate of soda and bismuth were principally employed on account of the property possessed by the latter of covering the mucous membrane of the stomach. It was much more useful to bring the walls continuously into contact with weak alkaline fluids, with the mineral waters of Carlsbad, Ems, Tarasp, etc. The first named, according to Jawoski's experiments, had the property, by its steady use, of checking the acid secretion, or of converting it into its opposite. Washing out the stomach with solution of common salt and the treatment by nitrate of silver introduced by G. Johnson were noted, and the frequent good effects of the latter. Condurango had a favorable influence. The most important advance of recent times was washing out the stomach. In old cases it was strongly to be recommended, but in those of recent origin there was danger of hemorrhage being induced. Moreover, some patients submitted to it with difficulty. It acted as a reliever of pain and an excitor of appetite; constipation and dilatation of the stomach ceased, and healing often took place.

The question of definite healing was a very difficult one. He had once had the experience of a patient coming one day to thank him for curing him of an ulcer of the stomach, and of being invited the next day by the patient's regular attendant to the post-mortem examination. On his return journey home he had committed gross errors of diet, and on the day following his ulcer gave way. It was to be noted that patients were frequently weeks and months without pain, with the ulcer still present, the pain at once returning on indigestible food being taken. It was, therefore, advisable to extend the treatment until the weight had increased, spontaneous pains had ceased and tenderness on pressure was no longer present. It was not possible with our present methods to prove a definite cure with absolute certainty. —*Medical Press*, July 18, 1888.

For Chapped Nipples.—

℞.—Salol . . . . . 1 part.
Ether . . . . . 1 "

Dissolve and add elastic collodion thirty parts.—*Gazette de Gynécologie*, July 15, 1888.

Treatment of Gout.—Prof. Jaccoud recommends a copious diluent draught and an exclusive milk diet in the treatment of gout; in cases in which there is considerable fever he gives a small quantity of hydrate of bromal. Preparations of colchicine and of salicylate of soda, though excellent as anæsthetics, are to be avoided. In patients affected with interstitial nephritis these substances produce most serious toxic symptoms.—*British Medical Journal*, July 21, 1888.

The Treatment of Chronic Diarrhœa with Silicate of Magnesium.—At the last session of the Paris Société Médicale des Hôpitaux, Debove recommended the silicate of magnesium in the treatment of chronic diarrhœa. He gives five drachms to two ounces daily, in milk. In phthisical patients, who had suffered with diarrhœa for three to five months, the results were marvellous. Obstinate constipation usually follows the administration of the powder. As the diarrhœa of phthisis is due to organic changes (intestinal ulceration), the diarrhœa soon recurs, in consequence of which the continued administration of the preparation in smaller doses becomes necessary. It is an important fact that the use of powdered talc permits of the administration of substances which would otherwise not be borne by tubercular patients. Thus they readily take milk, which ordinarily causes diarrhœa; and Debove has by this means been enabled to give some patients as much as an ounce and a half of oil daily, much to their benefit. Already on the second day after the administration of the powder the stools are no longer white. The lightness of the powder favors its rapid elimination by the intestinal canal.—*Wiener medizin. Presse*, July 1, 1888.

Tannin in Dilatation of the Stomach.—Dr. H. Boulland, thinking that tannin—which acts on the retractibility of the mucous membrane, and is at the same time absorbent and antiseptic—might be useful in dilatation of the stomach, has employed it in many cases with success. In cases in which constipation was present, Dr. Boulland administered doses of 10 centigrammes (1½ grains) instead of 20 centigrammes (3 grains). By this means the regularity of the bowels was not interfered with, and the dilatation decreased in proportions analogous to those obtained by washing out the stomach. In twenty days, the stomach was reduced nearly to its normal condition. At the same time, the patients took frequent but light meals, chiefly of pasty substances, and no starchy matter. When the dilatation is due to a tumor, tannin does not give better results than other methods. It diminishes mucous secretion, however, and renders the digestion less painful. Dr. Boulland has found the hemostatic properties of tannin equal to those of ergotin and perchloride of iron. In particular he has used it with success in many cases of epistaxis, when all other means had failed.—*British Medical Journal*, July 21, 1888.

Oil of Turpentine as a Hemostatic in Epistaxis.—In cases of obstinate epistaxis in which other means had failed, Dr. M. Eurye, of Budapest (*Orrosi Heti Szcuile*, 1887, 12), upon a recommendation in Billroth's *Surgery*, used tampons saturated with oil of turpentine, with surprisingly prompt success. In one case in which the bleeding had continued for eight days and resisted all internal and external measures, threatening acute anemia, the application of three tampons moistened with oil of turpentine at once permanently checked the hemorrhage. To prevent intense irritation of the nasal mucous membrane it might be well to dilute the oil.—*Medicin. Chirurg. Rundschau*, July 1, 1888, from *Wiener med. Bl.*, 1888, 13.

The Bacteriology of Yellow Fever.—Dr. Sternberg, who recently made to the President a report upon the yellow fever at Cuba, before returning home delivered a lecture

before the members of the Royal Academy of Sciences of Havana. There are considerable discrepancies between the results arrived at by Dr. Sternberg and those obtained by the Commissioner of the French Government, Dr. Gibier, which appeared in THE NEWS of last week. The whole subject appears to be fraught with considerable difficulty, and evidently requires a good deal more investigation for its proper elucidation.

In all ten necropsies made by Dr. Sternberg, he reserved for examination parts of the stomach and intestines, of the interior of the liver and kidneys, and also specimens of urine from the bladder and of blood from the heart. With these materials he reared cultures in meat-peptone jelly or agar-agar, and in some cases in solidified serum or peptonized broth.

In addition to the more common forms four other bacilli were found: α, from one and a half to three times as long as its breadth, with rounded ends, and occurring singly or in pairs. In its morphological aspects it appears to bear considerable resemblance to some common bacilli of putrefaction, but it differs from these in the appearance of its colonies in jelly. The deep colonies are lobulated and have a pale-brown color, and those which grow near the surface present a lobulated margin, which gives them the aspect of a rosette or of a flower with its petals open, like a daisy; β, shorter than α, possessing the property of end-staining in a more constant and marked manner; γ, a bacillus which liquefied jelly and developed a green pigment, probably the bacillus of green pus; and a bacillus which forms flat colonies of a glassy appearance with irregular borders and wrinkled in the interior, is also mentioned as requiring further study.

In eight out of ten cases the cultures from blood taken from the heart remained sterile; seven of the cultures from the urine, four of the cultures from the kidney, seven of the cultures from the liver were also sterile.

The bacillus α was found in one case in cultures from the blood, in one in those from the urine, in four in those from the kidney, in two in those from the liver, and in eight in those from the stomach and intestines. This bacillus Dr. Sternberg has not succeeded in obtaining from the digestive tract of other bodies, but he is not able to assert at present that it only occurs in yellow fever, much further investigation being needed to determine the question of its etiological relation to that disease.

Dr. Sternberg's experiments on animals having up to the present time yielded only contradictory results, he will have to repeat them before drawing any conclusions.

In the cultures from the kidney and the urine in the first case the α bacillus was associated with another bacillus resembling it. After a good deal of trouble he succeeded in separating this out and studying it in pure cultures. Dr. Sternberg does not now think that α is like the bacillus of Babes, as he was at first disposed to believe; it is more probable that β may be so. This forms pale-brown colonies in jelly, which have no lobulated margins like those which characterize the α colonies. The β colonies, too, grow more slowly, and in mixed cultures in jelly in Esmarch's tubes, the β colonies do not begin to appear until those of α have acquired a considerable size. The characters of β will have to be gone into more thoroughly at some future time.

In the cultures of the stomach and intestine a bacillus which liquefied jelly was obtained in three cases. This appeared to be identical with Dr. Gibier's bacillus. Dr. Sternberg thinks he might probably have met with this bacillus more frequently if he had used jelly instead of agar-agar in his earlier cases. This bacillus, which he designates as γ, is large and oval, with rounded extremities, and, like many other microörganisms, shows in highly colored preparations the property of end-staining. This, indeed, is common enough in old cultures of bacilli. There does not appear to be any reason for looking upon this as a spirillum, as Dr. Gibier is disposed to do. In Dr. Sternberg's cultures it has not presented the character which, the French Commissioner believes, points it out as the probable cause of the disease, no deposit of black pigment having been observed in any of the tubes—neither in cultures sown directly from those supplied by Dr. Gibier himself nor in those obtained by Dr. Sternberg from the intestinal contents.

In three cases portions of liver and kidney were preserved in the laboratory, wrapped in muslin or blotting-paper soaked in a one per cent. solution of bichloride of mercury. The examination of the interior of these fragments at the end of forty-eight hours demonstrated the existence of numerous and various microörganisms. In one case there was found in a specimen from the kidney a large micrococcus in tetrads, associated with a streptococcus and staphylococcus which liquefied jelly. With this exception, Dr. Sternberg has met with no microörganisms in any of the cultures from the interior of the body. On the other hand, in cultures from the surface he always found micrococci of various kind.—*Lancet*, July 21, 1888.

The Development of Gastric Cancer in the Cicatrix of the Round Ulcer.—FLATOW (*Inaug. Dissert.*, Munich, 1887) describes a case of gastric disorder in a female, aged twenty-six, from the symptoms of which the diagnosis of gastric ulcer was made. At her request, the patient left hospital uncured, to return after a few months. She manifested all the signs of gastric cancer and in twelve days died in collapse. The autopsy confirmed the diagnosis. At the pyloric extremity of the stomach, on the lesser curvature, there was a cancerous tumor, growing evidently from a distinct cicatrix, one and a half inches long and three-quarters of an inch wide. The statement of Hauser that cicatrized ulcers of the stomach dispose to the development of gastric cancer is strengthened by this observation. It also supports Virchow's view of the etiology of tumors—that they preferably arise at points exposed to frequent irritation.—*Centralbl. für klin. Med.*, July 7, 1888.

Cocaine in the Surgical Treatment of Hydrocele.—To diminish the pain caused by the injection of iodine M. ALEZAIS proposes the employment of cocaine as a local anæsthetic. The tunica vaginalis testis is punctured and its serous contents evacuated. An injection of a solution of cocaine, two and a half grains to the ounce of water, is then made into the cavity and permitted to remain a few minutes. This is followed by the injection of the ordinary solution of iodine, which causes no more pain than that of the contact of the fluid with the walls of the cavity. By the employment of this modification of the classical treatment of hydrocele, it becomes possible to substitute the pure tincture for the weak solution of iodine, at the same time increasing the dose of cocaine. —*Rev. Gén. de Clin. et de Thérap.*, July 5, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance . . . . . $5.00.
Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, AUGUST 11, 1888.

THE CÆSAREAN METHOD OF SÄNGER, AND THE CLAIMS TO PRIORITY.

No sooner is a new surgical method placed upon a sure basis by success than there is an effort made on the part of some one, to be perhaps followed by many others, to prove either that the operation was thought of long before, was tried at an earlier period by one or several other men, or that there is too great credit accorded for a new application of an old principle long taught. The Porro operation and the laparo-elytrotomy of Dr. T. G. Thomas had to pass through the fires of this form of criticism, and now we have to regret that repeated attempts are being made to show that before Dr. Sänger even published his new principles of uterine closure, other men, particularly in the United States, had practised the same methods of suturing with success.

It is true that the Sänger method of to-day is not precisely what it was in May, 1882, because resection of the muscularis and separation of the peritoneum are rarely required. Why? Because the object of these two steps—*i. e.*, the turning in of the peritoneum, so as to secure the serous surfaces in apposition, can be generally attained without them. The important steps of antisepsis—deep and superficial uterine suturing, multiplicity of stitches used in both rows and the application of the sero-serous method of closing the peritoneum, as in intestinal wounds, are all retained. The same ends are accomplished, although some of the means originally deemed essential have been found by experience not to be such, and the process has been wisely simplified. It is not generally known that Dr. Sänger was a successful Cæsarean operator before he wrote his first treatise upon the subject, and that it was the practical use of the uterine suture—old style—that led to the study which produced the improved method. Dr. Leopold's first operation was a Sänger, because he had become convinced that it possessed features which gave promise of success.

The claim that Dr. S. S. Lungren, of Toledo, Ohio, and Dr. Moses Baker, of Stockwell, Indiana, antedated in their operations the introduction of the method of Sänger by virtually adopting the same plan, rests entirely with other writers than themselves and requires a considerable departure from the language of their reports to establish. Other operators might much more justly be named as claimants than these two, both as to priority of time and close resemblance in technique.

Dr. Lungren says of his first operation, May 8, 1875: "Five silver wire sutures were now introduced to close the uterine wound. The sutures were entered about one-quarter of an inch from the edges of the incision and carried nearly through the substance of the uterus. Each one was twisted tightly twice only and the wire cut off close to the twist, which was then turned downward into the wound at right angles to the suture, care being taken to *approximate the edges of the peritoneum.*" There is certainly nothing peculiar in the manner of closure; a few deep sutures, no superficial ones, and the outer edges of the incision brought accurately edge to edge, as in an incised flesh-wound. Prof. D. Warren Brickell, of New Orleans, in 1867, closed the uterine wound in his Cæsarean case with six silver wire sutures in the same way and saved his patient.

In Dr. Moses Baker's operation, November 6, 1880, four sutures of carbolized silk were inserted in the same way, then tied and cut off near the knots. The woman and child were alive and well three years ago. If these were the same as the operation now called Sänger-Cæsarean, then Dr. Sänger cannot be said to have operated the thirteenth in order and two years and a half after Leopold, as Sänger performed a successful operation in August, 1880, or twenty-one months before Leopold's first case, using ten silk sutures, all deep, in the uterine wound, just as was done with silver wire in the Brickell and Lungren cases before his.

Quite a number of cases of uterine suturing might be quoted from American authors in which thread, silver and silk were used prior to the initial operation of Leopold, of Dresden, on May 25, 1882; but in no case was the discovery of Jobert de Lamballe (1824) and the method of intestinal closure of Lembert (1826) applied to the closing of the peritoneum in the uterine wound; in no case do we find proof that the serous surfaces of the peritoneal coat were placed in apposition (surface to surface, not edge to edge) in the uterine closure, or that more than ten sutures were inserted.

The nearest approximation to the Sänger method was made by Dr. R. O. Ingram, of Montezuma, Georgia, on September 18, 1874, when he inserted three rows of carbolized silk sutures in the uterine wound, viz., three deep, three half deep, and four peritoneal; but he did not welt in the peritoneum after the plan of Lembert in order to secure the most rapid union; his patient recovered.

We care little about the name of Sänger being given to the new Cæsarean operation, but we do care a great deal that he should not be robbed of the credit that is justly due him, first, in recommending two rows of multiple sutures to diminish individual tension and secure a tight closure; and second, the application of the intestinal suture and method of Lembert to the uterine peritoneum. This appears to be a simple matter, but why did not some one make the application years ago and thus save, as he has done, a large proportion of Cæsarean women? It is no discredit to him that he did not operate by his proposed method before Leopold. Dr. Sänger is a young man, is not a professor and has only a private hospital for the reception of patients. He has a large gynecological practice, but has not the opportunities for Cæsarean work that are possessed by those holding appointments to maternities, as Leopold, Zweifel, Breisky and others. It is, therefore, more to his credit that he stands in number of cases very near the head of the list of operators.

There have now been many more than a hundred of these operations, which are being performed at the rate of three per month, one-fifth of the whole belonging to our own country. We have gone through a trial of failures, the first five cases having been fatal; but have since done better, saving nine out of fifteen, several of the operations having been undertaken under conditions apt to render the result a fatal one for the woman, such as far-advanced cancer and Bright's disease. When the first chronological hundred can be arranged, it will probably be found that the mortality has been between twenty-five and thirty per cent. for all cases, favorable and unfavorable. We have a record of 36 cases for 1887, with 28 women saved, or nearly 78 per cent. Seven of the operations were American, with three deaths. Great Britain has at last entered into the trial, with two cases and two deaths: one woman had albuminuria, and the other, three fibroids in the line of incision, which became centres of purulent disintegration and prevented the union of the uterine wound. England appears to be peculiarly unsuccessful in all forms of Cæsarean work. Better subjects and a closer adherence to the German technique will, no doubt, produce more encouraging results. Her operators have very little faith in the Cæsarean section and strong prejudices against it, begotten by a mortality of about eighty per cent. in her past history. Of later years better work has been done, and we hope that the change will encourage her operators to make a more extensive trial of the new improvement.

Now that the operation is becoming less fatal in the United States, there is a growing disposition to depart from the technique of the Sänger method, by using fewer uterine sutures, by not turning in the peritoneum and by employing an uninterrupted suture instead of a number of Lembert stitches in its closure. We believe that every change has more or less risk in it and that the Lembert stitch, at short intervals, gives the best security against leakage. It may be true that union quickly takes place whether the peritoneal closure is made edge to edge or surface to surface; but after the successes of Leopold (eighteen saved out of twenty), we are not inclined to favor any departure from his example and go back to the earlier methods of uterine suturing. These departures are already creating trouble in making a true classification in certain German, French, English and American cases, when it is proposed to ascertain the mortality of the first hundred operations performed after what has been styled the Sänger method. Call the modern operation *New* or *Improved*, still it ought to have a certain established technique to be adhered to.

FOODS FOR INVALIDS AND INFANTS.

THE physician who is constantly prescribing foods for invalids and infants should be exceedingly cautious how he selects from the vast array of patent

foods upon the market, lest he unwittingly becomes a party to the ignorance, or deception and artifices of the vendors of some of these articles. Manufacturers are prone to vaunt the excellence of their special preparations and, often by the unwary aid of the chemist and the profession, are enabled to parade their advantages skilfully and effectively before the public. As Professor Leeds remarks: "Whatever characteristics in such foods are shown to be of most value, these characteristics the manufacturers claim that their special preparations possess; whatever constituents are of little value or indigestible, these constituents are asserted to be absent; whatever alimentary principles are easiest of digestion and most valuable in nutrition, these are asserted to be present." The physician owes it to himself and to his patients to sift these claims. He may not be able to conduct the analyses and experiments personally, in which case he should take advantage of the investigations of others well qualified to pursue them.

Some of the most useful inquiries conducted by State boards of health relate to this very subject. Special mention may be made of the recent investigations of Dr. Albert W. Leeds, the results of which are to be found in the last report of the Dairy Commissioner of New Jersey. These analyses and experiments relate to a number of well-known brands of infant foods and foods for invalids. Some of them are what they purport to be, but the greater portion are said to be misrepresentations, having constituents or proportions of constituents not given in the circulars accompanying them, or not having constituents or proportions of constituents represented as being present. In other words, their claims in important particulars are not supported by the results of chemical analysis. One article of which mention is frequently made contained over fifteen per cent. of alcohol, a fact which classes it among alcoholic beverages instead of "highly nutritious foods."

The practitioner who would intelligently and conscientiously prescribe proprietary foods would do well to consult the Report alluded to, rather than accept without reserve the laudatory and frequently deceptive circulars which accompany these articles; otherwise he may do injustice both to himself and to those who rely upon his skill and good judgment.

An Army Medical Board will convene in New York City, October 1, 1888, for the examination of such persons as may be properly invited to present themselves before it as candidates for appointment in the medical corps of the army. Application for an invitation should be addressed to the Secretary of War, stating date and place of birth; place and State of permanent residence, and accompanied by certificates, based on personal acquaintance, from at least two persons of repute, as to citizenship, character and moral habits; testimonials as to professional standing, from the professors of the medical college from which the applicant graduated, are also desirable. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, in evidence of which, his diploma must be submitted to the Board.

Further information regarding the examinations and their nature may be obtained by addressing the Surgeon-General of the U. S. Army, Washington, D. C.

By a Ministerial decree of July 16th, committees have been designated to organize the following International Congresses, to be held at Paris during the Universal Exposition of 1889. Congress of Dermatology and Syphilography; Congress of Hydrology and Climatology; Congress of Hygiene; Congress of Physiology; and Congress of Therapeutics.

The Emperor of Germany has conferred the Order of the Star and Cross of the House of Hohenzollern upon Prof. von Bergmann; the Order of the Red Eagle of the Second Class with the Oak Leaf upon Prof. Gerhardt; and the Order of the Red Eagle of the Second Class upon Prof. Schrötter. These decorations are supposed to indicate the views of the Emperor in reference to the medical aspects of the sad events in Germany of the past few months.

Prof. Hugo Ernst Heinrich Ruhle, Director of the Medical Clinic of Frederick William University of Bonn, died on July 11th, aged sixty-four years. He was born at Lieguitz and finished his studies at Berlin. In 1857 he was made professor extraordinary and director of the medical clinic at Breslau. In 1860 he was called to the University of Griefswald, remaining until 1864. From this time on he was associated with the University at Bonn.

Dr. Julius Ludwig Budge, Professor of Anatomy at the University of Griefswald, died on July 14th, aged seventy-seven years. Budge belonged to that group of investigators who have taken part in the advances which physiology and practical medicine

have made in the last decade. Among his important works were *Movements of the Iris*, which was awarded prizes by the Paris Academy of Medicine and the Brussels Academy of Medicine; *Investigations upon the Influence of the Central Nervous System upon the Movements of the Bladder*; and *The Course of the Bile Passages in the Liver*. Budge was educated at Marburg, Berlin and Würzburg and settled at Bonn, where he was made professor. He was made Professor of Anatomy and Physiology at Griefswald in 1856.

REVIEWS.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION, FOR THE YEAR 1887. Volume IV. Edited by ALFRED L. CARROLL, M.D. 8vo., pp. 554. New York: J. H. Vail & Co., 1888.

THIS volume of *Transactions* contains numerous papers upon practical subjects well worth the attention of the profession. In addition, we find these discussions at length—upon "The Management of Compound Dislocation of the Ankle-joint;" "Typhoid Fever;" and "Placenta Prævia." The President, Dr. Isaac E. Taylor, of New York, contributes the illustrated article of the volume, upon "Lupus of the Cervix Uteri and Female Genitalia." The book is especially interesting for its "Memoirs of Dr. Alonzo Clark," an excellent picture of whom forms its frontispiece.

We have been especially interested in the discussion on "Placenta Prævia." The mechanism of placental separation and the causation of hemorrhage are clearly set forth by Dr. Harrison, who opened the discussion. Dr. Taylor stated the results of studies and demonstrations made in 1852 and subsequently, which he published in 1862, which proved the anatomical facts stated recently by Hofmeier, regarding the structure of the cervix uteri and its behavior during gestation and labor.

Dr. Taylor believes that the cervix remains distinct until labor; that the placenta is in the body and not the cervix uteri; and that hemorrhage when the placenta is prævia is caused by uterine diastole, and not systole. Dr. Taylor claims priority in the discovery of these facts, and we are not inclined to dispute his claim.

The pith of the discussion is in the statement of the treatment to be employed, by Drs. Thomas and Lusk. This is, briefly, after the seventh month, the induction of labor; preferably by bi-polar version, rupture of the membranes, deliberate extraction, using the fœtus as a tampon; Barnes's dilators and the hot douche, if needed, to secure dilatation.

The volume contains much valuable matter and reflects great credit upon the Association from which it emanates.

CORRESPONDENCE.

TREATMENT OF STRICTURE.

To the Editor of THE MEDICAL NEWS,

SIR: My attention has recently been called to an article in your issue of July 14th, entitled "The Rational Treatment of Stricture of the Male Urethra," by Dr. J. H. Girdner, in which a series of statements are made which are at variance with careful statistics and the published experience of many well-known authorities on this subject.

That the tightness of a stricture depends upon the *amount* of plastic connective tissue thrown out is not in accordance with either pathological research or clinical experience, for, as a matter of fact, the *amount* of plastic material at first usually encroaches but little on the urethral calibre, but it is its contraction that is responsible for the narrowing of the urethral lumen. Thus, we do not find tight strictures appearing immediately after inflammatory action has taken place—*i. e.*, the time at which the plastic exudate occurs—but years after, owing to its gradual contraction, and the contracting band may be found to consist of a *mere thread* of connective tissue.

In spite of long and careful statistics to the contrary,[1] the author gives his dictum that the majority of strictures occur in the bulbous and membranous portions of the urethra, an old error, due either to faulty methods or means of diagnosis or to limited opportunity for investigation. The explanation that these portions, being the most dependent, the gonorrhœal poison naturally gravitates to and remains in them, is scarcely logical, unless we consider that gravity has no effect upon the pendulous portion, or that these patients suffer from constant priapism.

Against the operation of internal urethrotomy he urges that a stricture cannot be cut internally, without, at the same time, "cutting some of the sound tissue in its neighborhood." An objection which might apply to most surgical operations and most certainly does in the case of external section, which he advocates in the same article.

The author, moreover, has evidently not coped with urethral antisepsis; in a very large number of these cases under my observation, both in private and hospital practice, I have never seen a serious accident due to septic injection. It is needless to have the wound "constantly bathed in urine," or to have urine come in contact with the wound at all, for by the proper use of the catheter, the urine may be kept from the cut surfaces for any length of time necessary to healing; and if the author finds that with his "best care" he cannot prevent the introduction of septic instruments, his methods of asepsis are indeed faulty. I would call his attention to the valuable work of Dr. A. G. Gerster, *Aseptic and Antiseptic Surgery*, p. 312. The experience of that author "extends over twenty-one cases, in which strictures were cut successfully from within; *no febrile or inflammatory complications were ever observed*;"[2] so much for sepsis.

In regard to deep strictures, the author very properly resorts to external section, claiming that this cures by the introduction of a wedge of *sound tissue* between the cut surfaces. It would be interesting to have him explain by what law of nature *sound tissue* is introduced between the surfaces in the repair of a wound in the urethra made from the outside and *contracting connective* tissue between the surfaces of a wound made in the opposite direction. Both clinical and pathological[3] investigation

[1] Otis: Stricture of the Male Urethra, its Radical Cure, p. 97.

[2] Italics my own.—W. K. O.

[3] See report of Dr. Stuart Eldridge, Otis on Stricture, Appendix.

have shown that healthy tissue is deposited in both cases.

In regard to the author's method of treating stricture of the penile portion, it is by no means novel and has, to my knowledge, been used by various surgeons with a certain amount of success in *recent* deposits of lymph along the urethral canal. Clinical experience, however, which overrides theory, however plausible on the surface, proves that, so far as organized strictures are concerned, the procedure is wholly inefficient to effect a cure.

Very sincerely yours,

William K. Otis.

5 West 50th Street, New York, July 20, 1888.

NEWS ITEMS.

The New Quarantine Act.—The following is the text of the quarantine act which passed the Senate May 3, 1888, passed the House July 23, 1888, and was approved by the President August 2, 1888. Its provisions go into immediate effect, and the quarantine buildings will be erected as soon as practicable. Steps will be immediately taken to secure sites for the quarantines not now on Government land:

An Act to perfect the quarantine service of the United States.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That whenever any person shall trespass upon the grounds belonging to any quarantine reservation, or whenever any person, master, pilot or owner of a vessel entering any port of the United States, shall so enter in violation of section one of an act entitled "An act to prevent the introduction of contagious or infectious diseases into the United States," approved April twenty-ninth, eighteen hundred and seventy-eight, or in violation of the quarantine regulations framed under said act, such person, trespassing, or such master, pilot or other person in command of a vessel shall, upon conviction thereof, pay a fine of not more than three hundred dollars, or be sentenced to imprisonment for a period of not more than thirty days, or shall be punished by both fine and imprisonment, at the discretion of the court. And it shall be the duty of the United States attorney in the district where the misdemeanor shall have been committed to take immediate cognizance of the offence, upon report made to him by any medical officer of the Marine-Hospital Service, or by any officer of the customs service, or by any State officer acting under authority of section five of said act.

Sec. 2. That as soon after the passage of this act as practicable, the Secretary of the Treasury shall cause to be established, in addition to the quarantine established by the act approved March fifth, eighteen hundred and eighty-eight, quarantine stations, as follows: One at the mouth of the Delaware Bay; one near Cape Charles, at the entrance of the Chesapeake Bay; one on the Georgia coast; one at or near Key West; one in San Diego Harbor; one in San Francisco Harbor; and one at or near Port Townsend, at the entrance to Puget Sound; and the said quarantine stations, when so established, shall be conducted by the Marine-Hospital Service under regulations framed in accordance with the act of April twenty-ninth, eighteen hundred and seventy-eight.

Sec. 3. That there are appropriated for the purposes of this act the following sums, out of any money in the Treasury not otherwise appropriated, for the construction, equipment and necessary expenses of maintaining the same for the fiscal year ending June thirtieth, eighteen hundred and eighty-nine.

For the Delaware Breakwater quarantine: Construction of disinfecting machinery, steam tug, warehouse, officers' quarters and expenses of maintenance for the fiscal year eighteen hundred and eighty-nine, seventy-five thousand dollars.

For the quarantine station near Cape Charles, Virginia: For the purchase of site, construction of wharf, repair of present hospital buildings and officers' quarters, disinfecting machinery, steam-tug, expenses of maintenance for the year eighteen hundred and eighty-nine, one hundred and twelve thousand dollars.

For the South Atlantic Station (Sapelo Sound): Construction of disinfecting machinery, warehouse, wharf, small boats and expenses of maintenance for the year eighteen hundred and eighty-nine, thirty-eight thousand five hundred dollars.

For the quarantine near Key West: Purchase of site, construction of disinfecting machinery, warehouse, small boats, steam-tug, hospital buildings and officers' quarters, expenses of maintenance for the year eighteen hundsed and eighty-nine, eighty-eight thousand dollars.

For the Gulf quarantine (formerly Ship Island), provided for by the act of March fifth, eighteen hundred and eighty-eight, in addition to the amount appropriated by the act approved March fifth, eighteen hundred and eighty-eight: For the expenses for the year ending June thirtieth, eighteen hundred and eighty-nine, fifteen thousand dollars.

Quarantine station, San Diego Harbor, California: For the purchase of site and the construction of disinfecting machinery, warehouse, small boats, hospital buildings, officers' quarters, and for expenses of maintenance for eighteen hundred and eighty-nine, fifty-five thousand five hundred dollars.

For the quarantine station at San Francisco, California: Hospital buildings and officers' quarters, disinfecting machinery, warehouse and wharf, steam-tug, small boats, expenses for the fiscal year eighteen hundred and eighty-nine, one hundred and three thousand dollars.

For the quarantine station at Port Townsend: For the purchase of site, construction of disinfecting machinery, warehouse, small boats, hospital buildings and officers' quarters, for expenses of maintenance for the fiscal year eighteen hundred and eighty-nine, fifty-five thousand five hundred dollars.

Disinfecting Clothes by Steam.—According to the New York *Tribune*, one of the busiest places in the city, in case of a serious epidemic of contagion, would be the ground floor of the Reception Hospital, in East Sixteenth Street, for there is the new disinfecting apparatus of the Health Department. Experiments to ascertain the most practical method for using heat in the destruction of disease germs have been conducted there since last winter. A tank of boiler iron, big enough for a dozen men to walk about in at one time, and having a strong iron door at each end, is the chief part of the apparatus. It is connected with a furnace and steam boiler by means of

pipes. The coils of pipes are close together inside the tank, and there is an arrangement of stop-cocks by which an operator can fill the tank with steam or dry heat at will. Dry air has been heated to a temperature of nearly 300° inside the tank.

When the apparatus was built the Health Board expected to be able to disinfect clothing and bedding by dry heat. Dr. Cyrus Edson knew that work of that kind had been done in Europe and he was anxious to make a trial. The Health Board has been making liquid disinfectants in the big room where the tank and boiler were set up. From a trough, in which water was passed over copperas, a strong solution of sulphate of iron was obtained, but it was used chiefly for disinfecting street gutters and the back yards of crowded tenement houses. A vile-smelling liquid, made by mixing vitriol with dead oil, was used in some tenement houses where the inmates thought that a disinfectant must smell strong to be effective. For the fumigation of rooms in which there have been cases of contagious disease the sanitary officials have used burning sulphur. It was the rule to burn up the bedding and clothing which had been in contact with smallpox or typhus-fever patients.

Dr. Edson and the Health Commissioners believed that the spread of diphtheria and of scarlet fever in the city might be checked if the department had means for the better disinfection of clothing and bedding. It was said that sulphur fumigation could not be depended on for the destruction of the germs of either disease in the clothing of patients and attendants. At the same time the Health Board could not compel the burning of bedding and clothing in the hundreds of cases of diphtheria and scarlet fever reported every month. Then there was the possibility that Asiatic cholera might come to the city and that the disinfection of clothing on a large scale might be imperative. It was believed that infected clothing could be placed in the new tank, subjected to dry heat for an hour or so, and then removed uninjured and free from the germs of disease. Experiments were begun to ascertain how many degrees of heat could be employed to kill the germs and yet not destroy the clothes. The result has been a change from dry heat to steam.

It was found that a few strong fabrics, which were placed in the tank dry and subjected to a dry heat of about 250°, came out purified and comparatively uninjured. An expensive carpet, belonging to one of Commissioner Bryant's friends, was ruined by exposure to 280° of heat in the tank for two hours. Another carpet, which had been left out in the blizzard and was partly frozen when it was placed in the tank, was subjected to a like test. Part of the carpet was burned up, while another portion was still frozen when it was removed from the tank. Subsequent experiments have shown that a roll of wet cloth may be subjected to intense dry heat several hours without being disinfected. It is believed that an envelope of steam protects the inner part of the roll from the heat.

By injecting live steam into the tank, Dr. Edson's assistants have been able to disinfect clothing and bedding at a temperature of about 160°, and the goods come out of the tank unhurt, except that the colors in some kinds of cloth are effaced or badly mixed. The disinfection by steam is rapid and satisfactory. Iron cages are being prepared for the collection and return of bedding and clothing. Each cage has a lock to it, and the owners of clothing can keep the key while the goods are being disinfected. The work is done by the Health Department, free of charge.

The Congress of American Physicians and Surgeons, Washington, September 18th, 19th and 20th.

The American Gynecological Society announces the following preliminary programme:

On the New Cæsarean Section, by William T. Lusk, M.D., of New York.

The Cause and Treatment of Urethrocele, by Thomas Addis Emmett, M.D., of New York.

Ureteritis, its Diagnosis and Symptomatology, by Howard A. Kelly, M.D., of Philadelphia.

High Amputation of the Uterus for Cancer, by Thaddeus A. Reamy, M.D., of Cincinnati.

The Technique of Vaginal Hysterectomy, by E. C. Dudley, M.D., of Chicago.

A Case of Rupture of the Uterus in Labor at Term, the Child born alive, the Mother subsequently having a full-term Child in Normal Labor, by C. M. Green, M.D., of Boston.

The President's Address, by Robert Battey, M.D., of Rome, Ga.

The Etiology, Pathology and Treatment of Anteflexion of the Uterus, by T. Gaillard Thomas, M.D., of New York.

Some Cases of Nerve Prostration in which the Remote Effects of Anæsthesia by Ether were bad, by William Goodell, M.D., of Philadelphia.

Cystokolpocele complicating Labor and Pregnancy—a supplemental contribution, by Samuel C. Busey, M.D., of Washington.

Adenoma of the Fundus Uteri, by James R. Chadwick, M.D., of Boston.

A Case of Extrauterine Pregnancy, by B. F. Baer, M.D., of Philadelphia.

On the Treatment of Extrauterine Pregnancy, by Joseph E. Janvrin, M.D., of New York.

On the Treatment of Pelvic Abscess, by R. Stansbury Sutton, M.D., of Pittsburg.

A Case of Subinvolution cured by the Removal of the Appendages, by Howard A. Kelly, M.D., of Philadelphia.

Some Points learned from an Experience of Thirty-four Ovarian Operation, with but one Death, by Joseph Tabor Johnson, M.D., of Washington.

The American Neurological Association will hold a discussion on "The Relation of Renal Diseases to Diseases of the Nervous System," "Cases of Trauma, wtih well-defined Lesions of the Central Nervous System" and on "Muscular Dystrophies."

The following papers will be read:

Post-hemiplegic Disturbances of Motion in Children, by Philip C. Knapp, M.D., of Boston.

Heat Centres in Man, by Isaac Ott, M.D., of Easton.

The "Ape-fissure," so-called, in Man, by Burt G. Wilder, M.D., of Ithaca.

Clinical Report of Cases of Epilepsy following Cerebral Hemiplegia, by E. D. Fisher, M.D., of New York.

The Relation of Urinary Changes to Functional Nervous Diseases, by C. L. Dana, M.D., of New York.

The Differential Diagnosis between General Paresis, certain forms of Intracranial Syphilis and the Cerebral

Type of Disseminated Sclerosis, by Landon Carter Gray, M.D., of New York.

Report of a Case of Primary Lateral Sclerosis, with late Cerebral Symptoms, due to Cyst of the Floor of the Lateral Ventricle, with Microscopic Report, by Wharton Sinkler, M.D., of Philadelphia.

A Case of an Unusual Form of Myxœdema, illustrated by Photographs and Sections of Excised Tissues, by F. X. Dercum, M.D., of Philadelphia.

A Case of Alcoholic Multiple Neuritis, with Sections, by James Hendrie Lloyd, M.D., of Philadelphia.

Observations and Experiments respecting the Pathology of Neuritis, by James J. Putnam, M.D., of Boston. Dr. C. K. Mills and others will demonstrate specimens.

Myositis Subacuta Progressiva, by George W. Jacoby, M.D., of New York.

The Differential Diagnosis between Peripheral Neuritis and those Cerebral Affections with which it is most likely to be Confounded, by E. C. Spitzka, M.D., of New York.

Nervous Affections following Injury, by Philip C. Knapp, M.D., of Boston.

Hereditary Chorea, by Wharton Sinkler, M.D., of Philadelphia.

Aneurism of an Anomalous Artery causing Anteroposterior Division of the Optic Chiasm and Bitemporal Hemianopsia, by S. Weir Mitchell, M.D., of Philadelphia. To be read by F. X. Dercum, of Philadelphia.

A Case of Focal Epilepsy with Observations on Trephining, by James Hendrie Lloyd, M.D., of Philadelphia.

The preliminary report of the Committee on Encephalic Nomenclature will be read by Burt G. Wilder, M.D., Chairman, of Ithaca.

The Southern Surgical and Gynecological Association.—The following preliminary announcement has been issued of the papers to be read at the first annual meeting of this Association, to be held at Birmingham, Alabama, September 11th, 12th and 13th next:

The President's Annual Address, by W. D. Haggard, M.D., of Nashville, Tenn.

The Annual Oration, by W. F. Hyer, M.D., of Holly Springs, Miss.

Floating Kidney, with Vicarious Menstruation, by DeSaussure Ford, M.D., of Augusta, Ga.

Gastrostomy, by W. B. Rogers, M.D., of Memphis, Tenn.

The Medical Treatment of Fibroid Tumors of the Uterus, by Bedford Brown, M.D., of Alexandria, Va.

Indications for Operative Interference in Cerebral Troubles, by T. O. Summers, M.D., of Jacksonville, Fla.

A Case of Tubal Pregnancy, Presenting Interesting Medico-Legal Relations, by E. P. Sale, M.D., of Aberdeen, Miss.

Superinvolution of the Uterus following Trachelorrhaphy, by Virgil O. Hardon, M.D., of Atlanta, Ga.

I. Dermoid Cysts of the Coccygeal Region, and

II. Electrolysis in Gynecology and Surgery, by E. J. Beall, M.D., of Fort Worth, Texas.

Alexander's Operation, by W. L. Nichol, M.D., of Nashville, Tenn.

Hysterectomy in Cancer of the Uterus, by W. H. Wathen, M.D., of Louisville, Ky.

The Extravagancies and Impracticable Requirements of Modern Antiseptic Surgery, so far as the Country Practitioner is Concerned, by J. M. Taylor, M.D., of Corinth, Miss.

Treatment of Fractures with Plaster-of-Paris Splints, by W. F. Westmoreland, Jr., M.D., of Atlanta, Ga.

The Present Status of Electro-Therapeutics in Gynecology, by J. R. Buist, M.D., of Nashville, Tenn.

Antiseptics in Surgery and Gynecology, by F. T. Meriwether, M.D., of Asheville, N. C.

The Attitude of Removal of Uterine Appendages for the Cure of the Convulsive Neuroses, by W. Locke Chew, M.D., of Birmingham, Ala.

Interesting Cases of Surgery, by R. M. Cunningham, M.D., of Pratt Mines, Ala.

My Antiseptic Bags, or Practical Aseptic Surgery, by J. W. Long, M.D., of Randleman, N. C.

The New Departure in Uterine Therapeutics—the Dry Method, by T. A. Means, M.D., of Montgomery, Ala.

A Study of the Various Methods of Treatment of Laceration of the Perineum and Rectocele, with Report of Cases, by J. H. Blanks, M.D., of Meridian, Miss.

Report of a Case of Spinal Concussion, by John R. Page, M.D., of Birmingham, Ala.

Fractures of the Forearm, by John Brownrigg, M.D., of Columbus, Miss.

Some Practical Thoughts in Surgery, by James Guild, M.D., of Tuscaloosa, Ala.

Perineal Lacerations, by M. C. Baldridge, M.D., of Huntsville, Ala.

Electrolysis in the Treatment of Urethral Strictures, by S. M. Hogan, M.D., of Union Springs, Ala.

The Field and Limitation of Laparotomy, by I. S. Stone, M.D., of Lincoln, Va.

Operative Procedures in Hypertrophy of the Prostate, by R. D. Webb, M.D., of Birmingham, Ala.

Discussion on Abdominal Surgery, by Drs. John Herbert Claiborne, Duncan Eve, Paul F. Eve, W. T. Briggs and others.

The Association will convene in the hall of the Young Men's Christian Association, at 10 o'clock A.M., each day.

A Gift to the New York Pathological Society.—At a late meeting of the New York Pathological Society, Dr. G. C. Freeborn stated that Dr. J. M. DaCosta, of Philadelphia, the Middleton-Goldsmith lecturer for the present year, had declined to receive any compensation for his lecture and had requested the Society to apply the amount ($100) to any purpose which might seem desirable. The matter had been referred to the trustees, and they had decided that the most fitting tribute to Dr. DaCosta's generosity would be to purchase some microscopes for the use of the Society, and had requested the speaker to procure them. He had succeeded in getting two microscopes, one having an Abbé condenser and a one-fifth objective, the other having no condenser and being of a low power. The microscopes would be engraved with an inscription to the effect that they were the gift of Dr. DaCosta.—*Medical Record*, August 4, 1888.

Pasteur's Honors.—A calculation has been made of the number of decorations with which M. Pasteur has been honored by various Courts and States throughout the world. It seems that he is the owner of fifteen orders, of which only one is French. In addition he is an honorary doctor of all the great Universities of Europe, and a

member of eighty-three learned societies. Such a record as this is proof of the extent to which his work has been appreciated.

It has probably fallen to the lot of few *savants* to experience during their lifetime so full a recognition of their scientific labors as has occurred to M. Pasteur. The rewards of science are often tardy in their appearance, and their bestowal frequently comes too late in the day to be of any actual service. When, therefore, an exception to the rule occurs it is worthy of notice.—*Medical Press*, July 18, 1888.

The Value of Vaccination.—Zurich, according to a daily contemporary, is beginning to suffer from the effects of neglect of vaccination. Until 1883 a compulsory vaccination law was in force, but in that year it was repealed, the success of the anti-vaccinationists depending, it is said, upon the fact that not a single case of smallpox occurred in 1882. But in 1883, in every 1000 deaths, 2 were caused by smallpox; in 1884 there were 3 in every 1000; in 1885, 17; and in the first quarter of 1886 there were 85 deaths. While Europe is exhibiting folly by showing in some localities opposition to vaccination, Japan is deriving benefits from the recognition of its value. Nagasaki possesses a governor, named Kusaka, who is bent upon ridding the town of the diseases which formerly infested it. By means of a system of compulsory vaccination, rigorously enforced by the governor, smallpox, long a familiar scourge in the old town, has been practically stamped out.

Germany, too, is showing the effects of revaccination, and hitherto the freedom of German towns from smallpox has contrasted in a marked degree with a larger prevalence of this disease in other European towns where revaccination is not enforced. Probably the outcome of the experience of the present generation will be the enforcement of revaccination in the majority of civilized countries.—*Lancet*, July 21, 1888.

Recent Elections at the Royal Society.—Prof. Edmond Becquerel, of Paris; Prof. Hermann Kopp, of Heidelberg; Prof. Ed. F. W. Pflüger, of Bonn; and Prof. Julius Sachs, of Würzburg, have been elected foreign members of the Royal Society of London; the first, for his investigations into "The Influence of Light upon Matter, with Particular Reference to Phosphorescence;" the second, for his "Studies of Atomic Volumes and Boiling Points;" the third, for "Investigations in Physiology, with Especial Reference to the Irritability of Nerves, to Respiration and to Animal Heat;" and the last, for his "Investigations in Botany, particularly in Plant Physiology."

Adulteration of Tea.—A suit at law at Moscow, and various investigations, disclose that tea is being shamelessly adulterated. Of forty-four samples which were officially analyzed, four consisted of a mixture of tea and a certain kind of grass, four of the grass alone, and five of tea which had already once been used. In Moscow the police have found a number of barrels of sweepings intended for admixture with tea.—*Deutsche medizin. Wochenschr.*, June 28, 1888.

Liquid Paraffin in Cod-liver Oil.—It is now also reported from Russia that much of the cod-liver oil there has been adulterated with liquid paraffin, in some instances with as much as fifty per cent. Physically the adulterated oil cannot be distinguished from the pure.—*Pharmaceutical Record*, June 15, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 7 TO AUGUST 13, 1888.

KOERPER, EGON A., *Major and Surgeon* (U. S. Army).—Relieved from duty at Fort Keogh, Montana Territory, and ordered to duty at Fort Walla Walla, Washington Territory.—Par. 5, *S O. 175, A. G. O.*, July 30, 1888.

DEWITT, CALVIN, *Major and Surgeon* (U. S. Army).—Relieved from duty at Fort Sully, Dakota Territory, and ordered to duty at Fort Missoula, Montana Territory.—Par. 5, *S. O. 175, A. G. O.*, July 30, 1888.

CORSON, JOSEPH K., *Assistant Surgeon* (U. S. Army).—Leave of absence extended one month.—Par. 17, *S. O. 178, A. G. O*, August 2, 1888.

HARVEY, PHILIP F., *Captain and Assistant Surgeon* (U. S. Army).—Relieved from duty as assistant to the attending surgeon at Washington, D. C., and ordered to duty at Fort Keogh, Montana Territory.—Par. 5, *S. O 175, A. G. O.*, July 30, 1888.

MERRILL, JAMES C., *Assistant Surgeon* (U. S. Army)—Granted one month's leave of absence from August 2, 1888.—Par. 7, *S. O. 178, A. G. O.*, August 2, 1888.

GARDINER, JOHN DEB W., *Assistant Surgeon* (U. S. Army).—Will, on the expiration of his present sick leave of absence, report in person to the commanding officer at Fort Leavenworth, Kansas, for duty.—Par. 4, *S.O. 178, A. G. O.*, August 2, 1888.

GORGAS, WILLIAM C., *Captain and Assistant Surgeon* (U. S. Army)—Granted leave of absence for one month, to take effect on being relieved from duty at Fort Randall, Dakota Territory.—Par. 4, *S. O. 177, A. G. O.*, August 1, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING AUGUST 4, 1888.

HUDSON, A., *Medical Inspector*—Detached from the "Trenton" and ordered home.

WHITE, C. H., *Surgeon.*—Ordered to the "Trenton," via Panama.

JARVIS, JOHN F., *Assistant Surgeon.*—Ordered to the Receiving Ship "Franklin."

BATES, N. L., *Medical Inspector.*—Detached from the "Richmond," and ordered to the "Pensacola."

ANDERSON, FRANK, *Passed Assistant Surgeon*—Detached from the "Richmond," and ordered to the "Pensacola."

KITE, ISAAC W., *Assistant Surgeon.*—Detached from the "Richmond," and ordered to the "Pensacola."

JONES, W. H., *Surgeon.*—Detached from the "Pensacola," and ordered to the "Richmond."

STONE, E. P., *Assistant Surgeon.*—Detached from the "Pensacola," and ordered to the "Richmond."

MCCORMICK, A. M. D., *Assistant Surgeon.*—Ordered to special duty in the Bureau of Medicine and Surgery.

WIEBER, F. W. F., *Assistant Surgeon*—Reports arrival home, having been detached from the "Vandalia."

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

ON THE SURGERY OF THE BRAIN AND SPINAL CORD.

An Address delivered before the British Medical Association, Glasgow, August 9, 1888.

BY WILLIAM MACEWEN, M.D., F.R.C.S.,
SURGEON TO AND LECTURER ON SURGERY AT THE GLASGOW ROYAL INFIRMARY.

MR. PRESIDENT AND GENTLEMEN: Allow me to thank you for the exceptional honor you have conferred upon me by inviting me to address the British Medical Association on my "Recent Investigations in Surgery." It would have been more in harmony with my own feelings to bring before such a meeting the work of others, but this the form of invitation explicitly precludes. From among the various subjects which have engaged my attention it would have been difficult for me to single out one as especially worthy of notice. Fortunately I was so far relieved from that decision by receiving a very direct hint from one whose position in the Association demands respect. In obedience to that expressed wish I now venture to address you on the "Surgery of the Brain and Spinal Cord," a subject which has been of much interest to me, and which I hope may not prove uninteresting to you. In doing so it is necessary to premise, in the briefest possible form, the history of the evolution of cerebral surgery.

THE SURGERY OF THE HEAD IN THE PAST.

Lesions of the head have at all times held a prominent place in the annals of surgery; much has been done by surgeons before our day to advance the healing art as applied to this particular region. Their efforts were, however, chiefly directed to the superficial parts, the skull and its membranes, and were exclusively confined to the results of injury. Their operations were simple, undertaken for the most part upon the primitive evidence of direct visual and tactile observation. There is no reference made by them to cerebral surgery, as it is now known. The brain, whose function was at that time little understood, inspired fear: it was intimately associated with the seat of life, it was the mysterious dome of thought, it gave lodgement in its recesses to the soul, and was surrounded by all the mysticism which a highly speculative philosophy inculcated. Although surgeons did not share the popular belief that to touch the brain was to induce certain death, yet they had just grounds for concluding that to them it was practically inviolable. It was no want of boldness or lack of manipulative dexterity, in which, indeed, they greatly excelled, that determined this reluctance in dealing with brain lesions. *Post-mortem* examination revealed the fact that many cerebral lesions could have been easily reached had the surgeon only known during life at what particular part they had been situated. There were two formidable barriers to the advance of surgery in this region—first, the fact that the majority of intracranial operations were attended by inflammatory action, which so often prove fatal as to cause surgeons to shun active interference; and secondly, the brain was a dark continent, in which they could descry neither path nor guide capable of leading them to a particular diseased area, and did they attempt to reach it, it could only be by groping in the dark. Therefore, they were constrained to confine their efforts to traumatic lesions, and of these to such as afforded external indications of their presence, and which called out clamantly for relief. From the days of Pott to our own, there seemed to be a growing conviction, not only of the impotence, but of the positive harmfulness of active interference, so that the trephine was regarded as an almost obsolete instrument. Yet surgery was fully abreast of the physiology of the day. Such was the state of cranial surgery till 1870.

TWO FACTORS NECESSARY FOR THE INTRODUCTION OF CEREBRAL SURGERY.

However wishful one might be to extend the sphere of surgery to the brain, it was necessary first to adopt means whereby immunity from the inflammation which so constantly attended brain lesions could be secured, and secondly, to endeavor to gain a better physiological knowledge, in the hope that light might be shed upon the localization of cerebral lesions. In the wards of the Glasgow Royal Infirmary, Lister had formulated the theory and wrought out the practice of the antiseptic treatment of wounds, and already much had been done to dissipate the fears of surgeons regarding operations practised on other parts of the body. Experience gained by me showed that not only compound fractures of the skull, but large osseous defects in the cranial vault, accompanied by extensive loss of cerebral substance, were quite amenable to treatment, exhibiting no tendency to inflammatory action, as long as the tissues were preserved aseptic. When this held true of the rough and often septic lesions produced by machinery accidents, how much surer would well planned and carefully executed operations be? This conclusion was subsequently amply confirmed by the results of operations undertaken by me for the relief of injury in which the brain had to be exposed, and from which detached portions of it had to be removed. In such instances no inflammatory phenomena interrupted the even course of healing. A striking feature of these wounds of and operations upon the brain was the absence of false *hernia cerebri*, which had hitherto formed such a conspicuous complication of brain lesions in man, and which had so often marred the success of physiological experiments by extending the zone of irritation and by the fatal results which ensued. It was thus manifest that inflammation arising from exposure of, and operations upon the cerebrum, could be obviated under aseptic conditions.

Meanwhile many workers had been sedulously endeavoring to unravel the intricate and complex questions relating to the structure and functions of the brain. Previously the cerebrum was supposed to perform its function as a whole, in the same way as the liver, heart and kidneys perform theirs, there being no differentiation of function. Broca, in 1861, from observation on human pathology, isolated a particular limited area as the seat of the faculty of articulate language. This very important investigation foreshadowed the localization of function in other cortical centres, for if the existence of a definite function confined to an isolated area were admitted, then the question arose, how many other centres with specialized functions might there be? Broca's discovery was thoroughly iconoclastic, it shook the notion entertained regarding the unity of brain function to its foundation, it awakened thought and made men explore anew, with critical eyes, fields which previous investigators were supposed to have exhausted. Dr. Alexander Robertson, of Glasgow, suggested, in 1866, that there were separate sets of fibres for the conveyance of special motor impulses from the cortex. Hughlings Jackson, in 1869, stated that there were many limited areas on the brain connected with separated and distinctive functions, founding his opinion, not on speculative deductions, but on clinical experience, and on the direct observation of pathological facts. The inception of the idea that there was a portion of the brain whose function was related to motion was treated with extreme scepticism, and the suggestion was likely to have long remained a speculative question had it not been for the advent of another and more direct mode of examination. This new departure consisted in the performance of experiments upon the lower animals by Fritsch and Hitzig, who, in 1870, published an account of their observations. They demonstrated the existence of a series of circumscribed areas on the surface of certain of the cerebral convolutions, the electrical stimulation of which caused, on the opposite side of the body, coördinated movement in distinct groups of muscles. These were momentous facts, destined to revolutionize former ideas of cerebral function. But their full force and significance were not recognized, in this country at least, until Ferrier's observations on the brains of animals, undertaken to put to an experimental proof the views entertained by Hughlings Jackson, were published in 1873. Then the mind of the physiological world was fairly awakened. The suggestions of Hughlings Jackson, on the motor cortex, became crystallized. Another link in the unity of the plan of creation was manifest, as even in the higher and more complex brain of man parts existed whose function found homologous expression in that of the lower animals.

THE INITIAL HISTORY OF CEREBRAL SURGERY.

This extended physiological knowledge enabled cerebral lesions to be more accurately localized, while my experience showed by preserving aseptic the parts operated on surgical interference with the brain could be robbed of its chief danger.

I. *Case in which the symptoms of focal cerebral disease led to diagnosis of lesion in Broca's lobe, 1876.*—While in possession of this knowledge a case of cerebral abscess presented itself to me in July, 1876. The general symptoms of this affection were clearly manifest. A cicatrix on the forehead marked the site of an injury under which the skull was bare. Had this cicatrix been taken as a guide to the localization of the abscess and an operation performed there, no abscess would have been found. But other phenomena were exhibited which enabled its seat to be definitely recognized. A convulsion commenced on the right side and gradually involved the whole body, accompanied by loss of consciousness. On its cessation absolute hemiplegia of the right side was present and remained for two hours, during which the patient was aphasic. Both these phenomena became much less marked at the end of this period. From these symptoms the abscess was diagnosed to be situated in the immediate vicinity of Broca's lobe. It was evident that the whole of the base of the left third frontal was not involved in a destructive lesion, otherwise the aphasia would have persisted for a much longer period, and it was probable that Broca's area had become involved in the inflammatory zone surrounding the abscess. Trusting to these localizing symptoms, it was proposed to open the abscess aseptically by exposing Broca's lobe. Unfortunately, the result of a consultation was decidedly to negative this proposal. The parents then refused consent, notwithstanding the assumption by myself of the sole responsibility of advising and performing the operation. Thirty-six hours afterward the convulsions returned and persisted until a fatal issue ensued. After death the friends acquiesced in the proposal to have the operation performed, just as it would have been, had permission to do so been granted, during life. The skull was trephined, the brain exposed and an instrument was introduced through the third frontal convolution for half an inch, when pus flowed through the incision, proving the accuracy of the diagnosis, and giving poignancy to the regret that the operation had not been permitted during life. The abscess, about the size of a pigeon's egg, was situated in the white matter of the basis of the second and third frontal convolutions. The blade of the bistoury, which had been left *in situ* after insertion through the trephine opening, was found to have penetrated its outer wall. The congested zone in the periphery of the abscess extended from the anterior horn of the lateral ventricle to the cortex at the base of the second, but especially that of the third, left frontal convolution. Here the precise spot in the brain which the abscess occupied was accurately determined from the localizing phenomena induced by the focal lesion, which were trusted as indicating its position, though pointing to a different part of the brain from that which would have been selected had the seat of injury been accepted as a guide. The operation showed how easily the pus could have been evacuated, though the unfortunate refusal to allow it to take place during life leaves uncertain the ultimate issue; but, judging from my subsequent experience, worse cases have recovered after operation.

II. *Case in which motor phenomena were the sole guides to the cerebral lesion, 1879.*—In 1879 a case with definitely localizing motor symptoms was seen by me, occurring in a boy who had a fall six days previously, which occasioned some slight bruising about the face and head, accompanied by a shade of mental obscuration. At the termination of forty-eight hours he was so well that his parents could with difficulty be dissuaded from allowing him to rise from bed. On the sixth day he had a series of convulsions, the twitchings beginning in the left side of the face, gradually involving the left arm and subsequently the left leg, during which consciousness was preserved. Paresis of these parts remained, though sensation was unimpaired. On the following day there was a renewal of the convulsions, the parts being affected in the same order, but the convulsions persisted, and finally became general, with loss of consciousness. Those motor phenomena indicated a lesion on the right side of the brain, pronounced at the middle and lower portion of the ascending convolutions, as the face and

arm centres were the first to show evidence of stimulation. The lesion was of an irritative nature, such as might be occasioned by a spiculum of bone driven into the brain, or by a degree of pressure exercised on its surface. It was clearly not destructive, such as might be occasioned by severe cerebral contusion. Dr. Alexander Robertson was asked to see the case, and agreed with me that the motor symptoms presented a sufficiently clear guide to the localization of the lesion in the lower part of the fissure of Rolando. It was therefore resolved to expose that portion of the brain. As a preliminary the head was shaven, when a scarcely preceptible irregularity was detected in the cranial vault near the coronal suture. When the skull was exposed, a fissure was discovered running across the coronal suture. Trephining was performed at a point slightly behind the auriculo-bregmatic line, and midway between the external auditory meatus and the vertex. This point *happened* to correspond to the posterior extremity of the fissured fracture. There was no blood between the dura mater and the skull, but the dura had a very dark color. This membrane was opened, and gave vent to two ounces of fluid and coagulated blood contained in the subdural cavity. The operation was conducted aseptically, and the patient made an uninterrupted, typical, afebrile recovery. There was no recurrence of the fits; paralysis of the left arm soon disappeared, and he is living now and in perfect health.

III. *Case in which the symptoms exhibited pointed to lesion in frontal lobe, 1879.*—In 1879 an idiopathic case came under observation, in which the totality of the symptoms indicated a lesion in the left frontal lobe. It occurred in a patient, the subject of a small tumor above the left eyeball in the orbital cavity. A tumor had previously been removed by me from that position and had now recurred. Other symptoms had, however, meanwhile presented themselves. The left pupil was in a state of stabile myosis; there was obscuration of intelligence, slowness of comprehension, want of mental vigor and pain in the head. These pointed to the probability of a lesion in the left frontal lobe, but were not sufficient to permit a diagnosis to be made. The patient was, therefore, placed under the observation of an educated skilled nurse. Some weeks later a series of convulsions occurred, the initial stages of which were carefully recorded by the nurse, without which the key to the brain lesion, as indicated by the convulsions would have been lost, as when seen by me they had become general and threatened speedy dissolution. The convulsions were at the outset strictly limited to the right side, commencing in the face and arms, and confined to these two parts during the initial attacks. The leg on the same side was affected during the third seizure, and ultimately the convulsions became general with complete loss of consciousness. These phenomena were construed as indicating extension of the irritation to the lower and middle portions of the ascending convolution, and when this was considered along with the former evidence it was concluded that an irritative lesion existed in the left frontal lobe. On these grounds it was resolved to trephine midway between the centre of the ascending convolutions and the anterior aspect of the cranium. At this point a minute nodule, the size of a barley-grain, was detected on the outside of the skull. A large trephine was applied, a disk of bone removed, and a tumor of the dura mater, which was exercising pressure on the brain, was exposed. It was half an inch in thickness at this point, gradually becoming much thinner and spreading all over the anterior two-thirds of the frontal lobe. The tumor was, after a prolonged operation, carefully dissected out, along with the brain membranes where they were involved in the neoplasm. The patient rapidly recovered, was restored to perfect health and subsequently was able to gain her own livelihood. She lived for eight years afterward.

[Dr. Macewen then gave details of the other cases which occurred in 1883—one a tumor in the paracentral lobule, one an encephalitis round a clot situated in the ascending frontal convolution, one an intracranial effusion of blood in the lower part of the fissure of Rolando, all of which were successfully operated on.]

With the relation of these seven cases, all of which occurred prior to the end of 1883, the initial history of the movement ceases to be solely personal to myself. In December, 1884, Dr. Bennet and Mr. Godlee, assisted by Dr. Ferrier, had the first case operated on in London, in which a tumor was removed by Mr. Godlee from the brain.

A FEW POINTS REGARDING THE PRESENT ASPECT OF CEREBRAL SURGERY.

Reference may now be made to a few points regarding the present aspects of cerebral surgery. First, are the localizing motor phenomena reliable guides to the diagnosis of cerebral lesions situated in the motor cortex? My answer is unhesitatingly affirmative. Each case, however, requires to be studied on its own merits; the whole phenomena presented, the *unobtrusive* as well as the prominent features, must be carefully searched for, the degree in which each is present must be accurately measured, and the whole weighed and compared with former experience before drawing a conclusion. The various points upon which reliance is to be placed should be tested, wherever possible, by instruments of precision, instead of the rough impressions conveyed by the hand being trusted. In testing the power of the muscles in brachial paresis the dynamometer will impart much more accurate information than that which can be gained through the sense of touch, and occasionally shades of difference may be determined by it which would otherwise remain undetected. In many cases the evidences of focal lesions are so distinct that a diagnosis is easy; in others they are so intricate that a prolonged and minute investigation is necessary to decipher them, while there are still others in which the signs are so perplexing that at best an approximation only can be arrived at. To lay bare a certain known convolution on a cerebral surface, and observe the results of its stimulation, is an easier task than to take what appears to be a tangled skein of nerve phenomena, such as is presented by many lesions of the complex brain of man, and to relegate each to its true source, and infer from a study of the whole what particular parts of the brain are affected.

VIII. *Epilepsy, Jacksonian, induced by focal facio-lingual lesion. Removal of cyst from brain: cured*—In support of the foregoing the following instances are adduced, and a case is first presented in which the symptoms were so definite and precise that the dignosis was easy, and permitted me to perform the operation on first seeing the patient. He was twenty-two years of age, and suffered from epileptiform convulsions, each lasting from two to three minutes, and as they occurred on an average every five minutes, he consequently had over one hundred in twenty-four hours. The convulsions were limited to the tongue, the right facial muscles, and the platysma on the same side. When they subsided the parts remained paralyzed. Consciousness was retained throughout. Eight years previously he had received an injury to the head, after which his right arm became weak, the weakness persisting, though he was quite able to work. It was clear that an irritative focal lesion existed, confined to the base of the ascending convolutions, causing

a Jacksonian epilepsy. The only question was whether the base of the ascending parietal was involved as well as that of the ascending frontal. The contraction of the platysma on the opposite side has been asserted to be induced by stimulation of the base of the ascending parietal. Dr. Whitelocke reminded me, however, that the platysma is often supplied by a branch of the facial, so that a single lesion in the base of the ascending frontal would be sufficient to account for the whole phenomena. The operation was at once undertaken, when in the lower part of the ascending frontal a cyst about the size of a filbert was found situated partly in the cortical and partly in the white substance of the brain, and was surrounded by a narrow zone of encephalitis. In manipulating the medullary substance in process of removal of the cyst the patient, while under chloroform, had a convulsion confined to the same group of muscles as were affected in his fits prior to the operation. The convulsion ceased with the removal of the cyst, and he has never since had another. The wound healed firmly under one dressing, the paralysis of the facial muscle soon disappeared, and he has since been constantly at work. The power of the right arm has also been increased. Possibly the cyst might have caused indirectly slight pressure on, or had set up an inhibitory action of the middle portion of the ascending frontal. This case affords important evidence of the position occupied by the facio-lingual centre in man, and, on the whole, corroborates that assigned to it by experiments on the lower animals.

IX. *Protospasm of the hallux preceded by sensory impressions and followed by paralysis.*—In another instance a very definite protospasm, accompanied by a sensory impression, gave the key to the localization. It occurred in a girl aged seven, the subject of frequently recurring attacks of severe epileptiform seizures, followed by paralysis of the affected parts. At the onset of these attacks the patient first experienced in the great toe of the right foot a painful sensation of such severity as to cause her to scream out. Shortly after, that toe was firmly extended in tonic spasm, which lasted about five minutes. Sometimes this ended the attack. More frequently it was followed by clonic contractions of the muscles of the right foot, leg and thigh, where the convulsions often terminated. Occasionally they extended to the muscles of the trunk, then to those of the right side of the face and right arm, the contractions ceasing in the order of accession. Rarely did this involve the opposite side, and when they did the patient lost consciousness. Though there was motor paralysis in the affected parts, the cutaneous sensibility remained unimpaired. From the great number of fits which the patient had, following each other in rapid succession, occurring in parts affected with paresis, the result of former attacks, while the cutaneous sensibility remained unimpaired, and, from the limited area affected, it was concluded that the lesion was cortical. The sensory impression in the hallux, followed by tonic, and then clonic, contractions of the same parts, extending to the lower limb, pointed to the upper region of the ascendiag convolutions as the area of irritation. From the general condition of the patient and family history, the lesion was probably tubercular, and, if so, might be multiple. During operations the upper portion of the ascending convolutions was exposed, and, with the exception of a few tubercular nodules—the size of barley grains—adhering to the vessels over the upper part of the ascending frontal, there was nothing visible on the surface. On careful palpation of the ascending convolutions, there was found on the upper part of the ascending parietal a circumscribed nodule buried in the cerebral substance, which, on exposure, by cutting through the gray matter, was seen to be a tubercular tumor, about the size of a hazel-nut, which was easily shelled out. As an immediate result, there was prolonged trepidation, of an erratic kind, affecting the muscles of the right side of the body, but especially those of the arm and the leg. These were continuous for fully a week, thereafter gradually subsiding. There have been no fits for over a year, and the girl is now in excellent health. The marked sensory impression, which this lesion produced, supports Dr. Gower's opinion that the parts in the so-called motor area subserve a sensory as well as a motor function. The localization of the movements of the hallux in the upper part of the ascending frontal has not been borne out by this case (unless the minute barley-grain tubercular nodules attached to the vessels in the pia mater could account for the stimulation), the tumor being found in the upper part of the ascending parietal, but the whole lesion could be included in the ring which Beavor and Horsley place on the upper portion of the ascending convolutions.

With these data from my own experience, as well as from cases reported by Mr. Godlee, Mr. Horsley and many others, it is clear that the motor and sensory phenomena form reliable guides in localization of lesions in the central convolutions.

The diagnosis of cerebral lesions in non-motor regions may be made from sensory phenomena.—The following instance shows this, and is also an example of the difficulty of finding the exact clew to the lesion and how easily it may be overlooked.

X. *Psychical blindness, the key to a lesion in the angular gyrus. Removal; recovery. Medico-legal aspects.*—A man who had received an injury about a year previously suffered from deep melancholy, strong homicidal impulses, relieved by paroxysms of pains in the head of indefinite seat. Though the pain was excruciating he welcomed it, as it temporarily dispelled the almost irresistible desire to kill his wife and children or other people. Prior to receiving this injury he was perfectly free from impulses of this kind, and had led a happy life with his family. Behind the angular process of the frontal there was a slight osseous depression, which could not account for his symptoms. There were no motor phenomena, but on minute inquiry it was discovered that immediately after the accident, and for about two weeks subsequently, he suffered from psychical blindness. Physically he could see, but what he saw conveyed no impression to his mind. An object presented itself before him which he could not make out, but when this object emitted sounds of the human voice he at once recognized it to be a man who was one of his fellow-workers. By eyesight he could not tell how many fingers he held up when he placed his own hand before his face, though by the exercise of his volition in the act, and by other sensations, he was cognizant of the number. He had been in the habit of reading in the New Testament, and when he had so far recovered from his injury he wished to resume his reading. He knew where the book lay near his bed, and could put his hand on it in the dark. One day he stretched out his hand, took the book, recognizing it through the sense of touch, by its smooth leather covers and the deeply indented letters on its back; he opened it, saw what he considered must be the letters, and the blocking of them into divisions for the words, but they were unknown symbols to him, they conveyed no impression of their meaning, the memory of their sign was gone, it was a sealed book to him. These phenomena, however, gave the key to the hidden lesion in his brain. On operation the angular gyrus was exposed, and it was found that a portion of the internal table of the skull had been detached from the outer, and had exercised pressure on the posterior portion of the supra-marginal convolution, while a corner of it had penetrated and lay embedded in the anterior portion of the angular gyrus. The bone was removed from the brain and re-implanted in proper position, after which he became greatly relieved in his mental state, though still

excitable. He has made no further allusion to his homicidal tendencies, which previously were obtrusive, and is now at work.

Such cases of complete mind blindness are rare, and the definite localization in this case will assist in indicating in man what function the anterior portion of the angular gyrus and posterior portion of the supra-marginal convolution subserve.

In cerebral surgery, not only does one require to localize the lesion, to select suitable cases, but also, after exposing the brain and its lesion, to judge when to advance and when to hold the hand. In a case rightly localized from the motor symptoms, a tumor was exposed in the leg and arm centres, on the left side of the brain; but its dimensions were such as to cause me, after carefully contemplating them, to refrain from removing it, as it would have led to hemiplegia of a much more pronounced character than was present. Instead, the vessels which supplied it with nutriment and which ran into its substance from the surface were all ligatured, in the hope that this would effect a restraining influence on its growth. The patient recovered, and is considerably improved. Though the fits are not quite cured they are not so severe as formerly, and are somewhat altered in character.

ANCHORING OF THE BRAIN AND SOME OF ITS CONSEQUENCES.

When injury has been inflicted on the surface of the cerebrum, followed by plastic effusion and cicatricial formation, the superficial substance is apt to become soldered to the membranes, when these remain intact, which, in turn, may be soldered to the skull, or, in the event of their detachment, the brain may become directly adherent to the bone, by means of cicatricial adhesion. Thus the surface of the brain becomes anchored or soldered to its rigid walls. It has no longer the free play within its water bed to expand and contract according to the varying states of the circulation. Each variation produces a dragging of the brain at this spot, and through it the whole hemisphere, at least, is affected. Any sudden physical effort pulls on the brain, producing a slight shock, a momentary disturbance, just as if the cerebrum had received a blow. Vertigo results. People affected in this way cannot rise up quickly, or perform any sudden movement of the body or head, without experiencing a sensation of giddiness, which sometimes causes them to drop. Consequently they are often incapacitated from pursuing their usual avocation.

Following upon this the gray matter of the cortex, immediately surrounding the cicatrix, by the incessant movement, is apt to become unstable, and to produce fits. Some cases of traumatic epilepsy are thus caused. Further, if the cortical irritation be continued, encephalitis is occasionally produced, often appearing in a chronic form, and long remaining so, though susceptible of being lit up into an acute affection. If the temperature remains high, active interference is apt to induce an extension of the encephalitis. Operation in such cases should be, when possible, postponed. The disregard of this advice has, to my knowledge, in one instance, hastened the fatal issue, encephalitis becoming rapidly general.

REIMPLANTATION OF BONE TO FILL THE HIATUS IN THE SKULL.

Osseous defects in the cranial wall have hitherto remained permanent, the surgeon making no effort to fill the gap. The brain, in the majority of cases, has thus been exposed, the thin membrane forming an insufficient covering, the patient being doomed for the remainder of his life to wear some kind of plate as a protection from injury. Since 1873 the portions removed by me from the skull have been carefully preserved, rendered aseptic, divided into minute fragments and reimplanted. Whenever there has been immunity from suppuration, these have grown and the continuity of the osseous wall has been preserved throughout. In a case of injury nearly one-half of the left anterior portion of the skull was broken into fragments, which lay in a confused mass, mixed with brain substance, shreds of membrane, hairs, *débris* of lime and blood. The portions of bone were all rendered aseptic, divided into fragments and replaced, quite a mosaic work being thereby formed. On the tenth day a portion of the damaged scalp having sloughed, exposed four of the reimplanted pieces, two of which, lying side by side, presented a striking contrast—one being suffused with the pinkish blush of life, the other with the pallor of death. With the exception of two fragments which shed, all the others remained, grew and now form a firm, osseous wall affording complete protection. This case, operated on four years ago, will be shown at the demonstration in the Royal Infirmary, along with many others, where lesser defects have been filled. At the same time, a boy, whose humerus has been restored by bone grafting, will be presented. He was operated on ten years ago, and the bone has grown in length and thickness since.

STATISTICAL RÉSUMÉ.

Of twenty-one cerebral cases (exclusive of fractures of the skull or other immediate effect of injury) in which operations have been performed by me, there have been three deaths and eighteen recoveries. Of those who died, all were *in extremis* when operated on. Two were for abscess of the brain, in one of which the pus had already burst into the lateral ventricles; in the other suppurative thrombosis of the lateral sinus had previously led to pyæmia and septic pneumonia. The third case was one in which there existed, besides a large subdural cyst over the one hemisphere, extensive softening at the seat of cerebral contusion on the opposite hemisphere, accompanied by œdema of the brain. Of the eighteen who recovered sixteen are still alive, in good health, and most are at work, leaving two who have since died, one eight years after the operation, from Bright's disease, she in the interval being quite well and able to work; the other, forty-seven days after the operation after the abscess was perfectly healed, from an acute attack of tubercular enteritis.

SURGERY OF THE SPINAL CORD.

Turning to another portion of the nervous system, to which only brief allusion can be made, it is found that certain sensory and motor phenomena due to lesions within the spinal canal are amenable to operations which are attended by a measure of success sufficient to offer a prospect of relief to a distressing and hitherto regarded as a hopeless class of sufferers. The spinal membranes and the cord itself can be exposed and neoplasms and encroachments upon the lumen of the canal may be removed therefrom without unduly hazarding life. The

first operations of this kind were undertaken by me for the relief of paraplegia, due to angular curvature of the spine. In such cases pressure may be exerted on the cord either by connective tissue neoplasms or by direct displacement of the bodies of the vertebræ, both lessening the lumen of the canal. By lifting the laminæ from the affected part the tumor could be removed and relief at the same time given to the compressed cord, were the osseous walls in front found to encroach upon the calibre of the canal. This was successfully carried out by me first in 1883. By making an incision on the tips of the spinous processes and severing the tendinous connections, and then shelling the soft parts from the bone with periosteal elevators, the hemorrhage was so trifling as to be for the most part arrested by sponge pressure, and with suitable instruments the operation, though demanding care, was easy to perform.

Case of paraplegia with incontinence of urine and feces, due to connective tissue tumor at seat of angular curvature of spine, completely cured by removal of tumor and laminæ of vertebræ.—In 1882 a boy, aged nine years, came under observation suffering from complete sensory and motor paraplegia, with incontinence of urine and feces, which had existed for two years previously, but was absolute during the last eighteen months. For three years he had had angular curvature of the spine, most marked between the fifth and seventh dorsal vertebræ, for which he had been treated by extension and plaster jackets. When seen by me the curvature had become fixed by ankylosis of the bodies of the vertebræ. Treatment by extension and plaster jackets was, however, tried again under direct supervision in the hope of amelioration. It proved futile. The limbs were livid and cold, affected with marked spastic rigidity and with wasting of the muscles. The symptoms exhibited pointed to irritation and pressure of the spinal cord about the level of the sixth dorsal vertebra. The paralysis having existed slightly for two years and markedly for eighteen months, and showing no signs of amelioration under ordinary treatment, this operation was deemed expedient. Dr. Alexander Robertson saw this case, and agreed in the hopelessness of any other procedure than the operation. On May 9, 1883, the laminæ of the fifth, sixth and seventh dorsal vertebræ were removed. There was no pulsation in the portion of the cord diffused. Between the theca and the bone there was found a fibrous neoplasm of one-eighth of an inch in thickness, which was firmly attached to the theca, and covered about two-thirds of its circumference. This was carefully dissected off. The cord was then able to expand backward, and its pulsations, which up to this period were absent, began to show themselves, especially opposite the fifth dorsal. Twenty-four hours after the removal of the pressure the limbs had lost their livid color, were distinctly warmer, the spastic rigidity had greatly lessened, the sense of tickling the soles had returned, and that of touch had improved. The first return of movement was observed eight days after. Soon he had perfect control over his sphincters. Six months subsequently he was able to go about without support. Five years afterward he walked three miles to pay me a visit. He attends school regularly, joins in all the games, including football, and he says he feels quite strong.

A second but more aggravated case.—In 1884 another case was seen of a somewhat similar kind, though much more aggravated, the symptoms being so far advanced as to indicate organic changes in the cord itself, which rendered operation almost hopeless. It was only on the urgent and touching appeal of the girl herself that the operation was undertaken. A dense connective-tissue tumor existed between the bone and the theca, which was so firmly adherent to both that in some places the theca was elevated along with the neoplasm. The portion of the cord thus exposed was shrunken to about half its normal dimensions, and lay like an inanimate rod. After the elevation of a sufficient number of laminæ to expose a portion of the cord which pulsated, the pulsations were communicated to this rod, pushing it from above downward, but there were no distensile pulsations in the rod-like part of the cord. From the whole appearances presented at the operation it was considered that there was no hope of her recovering from her paralytic state. However, ten hours after the operation the limbs had lost their lividity, felt warm to the touch and the patient said she experienced a sensation as if she were dreaming that her legs were on and hot water was running through them. From the fourth day after the relief of pressure she had continence of urine and feces, for which alone, she declared, she would willingly have undergone the operation. Sensation quickly returned to the limbs; motion very slowly. Six months after she could move her limbs freely. Eight months subsequent to the operation she walked a quarter of a mile, stated she could perform many light duties in the house, besides attending to herself. She has since been very well and able to enjoy life.

A third case was also successful, but two others have not been so—one succumbed a week after the operation, the others some months later to an attack of tuberculosis. In both of these the temperature was high prior to the operation, and was subject to exacerbations, indicating an activity in the tubercular disease at some part distant from the ankylosed angular curvature. Since this experience no case has been deemed fit for operation in which the temperature did not run an even, regular and continuous afebrile course.

Paraplegia from traumatism, cured by elevating connective tissue tumor and depressed arch of twelfth dorsal vertebra.—From a coal-pit accident a man, twenty-two years of age, received a severe injury to the spine at the level of the lower dorsal vertebra, which caused absolute motor paralysis with incontinence. There was marked hyperæsthesia of the affected parts, which increased in severity during the first three weeks, so that he could not bear to have the floor shaken or his limbs touched. Between the third and fifth week a rapid change took place. At the termination of that period the muscles of the lower limbs would not respond to electricity, they had become so shrunken and wasted that the contour of the bones stood prominently out, and notwithstanding massage of the limbs after the cessation of the pain, the flexor muscles had markedly contracted, causing drooping of the feet and toes and fixation of the joints. Later, the skin over the bony prominences became red, pressure-points and bed-sores formed, irrespective of most scrupulous attention, the urine became ammoniacal and his temperature ran up. It was evident that a fatal issue was imminent unless an attempt to relieve the pressure on the spine was at once made. In February, 1885, this was done. The lower dorsal and the first lumbar vertebræ were exposed. The arch of the twelfth dorsal was found fractured and slightly depressed, and between it and the theca there existed a connective-tissue tumor, measuring nearly a quarter of an inch in antero-posterior diameter, and extending from the eleventh dorsal to the second lumbar vertebra. Both above and below the twelfth dorsal the tumor gradually shaded off to about one-half of its thickness at that point. It was confined to the posterior aspects of the canal. This tumor was carefully dissected from the theca. The same night there was a distinct improvement in the warmth of the lower limbs. He began to move his toes on the third day. A month afterward the contracted tendons about

the ankle and feet were extensively tenotomized to relieve the structural contractions, after which motor power rapidly increased. He was soon able to walk with support, which a year subsequently he discarded; and now he can move about with ease, but with paraplegic gait. [These last two cases were shown at the Pathological and Clinical Society, Glasgow, December 22, 1885, and published, appearing in the *Glasgow Medical Journal*, besides notes of them in the *British Medical Journal*.]

RÉSUMÉ.

Here are, therefore, six cases in which the elevation of the posterior laminæ of the vertebra has been performed. Four of these have completely recovered, and two have died; one of these from extension of tubercular disease months after the operation, and after the wound had healed, leaving one in which the operation possibly hastened the death of a patient who was otherwise in a painfully helpless and hopeless condition.

Such operations are now beginning to be practised by others. Mr. Horsley has, within this last year, published a successful case, in which a somewhat similar operation has been performed, for the removal of a small tumor of the theca, diagnosed by Dr. Gower.

In conclusion, let us remember that the same phenomena by which we are now able to recognize certain cerebral lesions and locate them in precise areas, were exhibited by patients who came under the eyes of our surgical predecessors, some of whom must have had the album of their memory filled with such impressions, yet they saw not their import. They were so hampered by the inculcated physiological dogma of the time that their true significance never dawned on them. The facts were reflected from their brain as objects from a mirror and no more. Gentlemen, there are all around us phenomena each with its hidden truth, obtrusively impressing our senses, and how do *we* fail to read their riddle?

ORIGINAL ARTICLES.

ICHTHYOL IN PULMONARY DISEASES.

By THOMAS J. MAYS, M.D.,
PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC.

Ichthyol, in common with many other valuable agents, has been introduced by the German medical profession, and it has already achieved a reputation which is likely to be permanent, at least so far as dermatology and surgery are concerned. Whether it will prove as effectual in internal as it has in external medication, remains to be determined by future research, and in the present paper I merely desire to direct attention to the possibilities of the drug in diseases of the respiratory organs.

Ichthyol, or fish oil, its literal English meaning, is a product which is distilled from a bituminous rock discovered about six years ago, in the Tyrol, near Seefeld. According to Professor von Fritsch, the bitumen of this rock constitutes the remains of decomposed animal matters, chiefly derived from fish; hence its name. "The products of distillation of this rock are treated with sulphuric acid and the resulting substance is neutralized either with ammonium or sodium, and the ammonium or sodium ichthyolate is obtained, which consists of a thick fluid resembling tar in appearance. It differs from known tars, vegetable and mineral, not only in odor, but especially in its physical properties. It is soluble in water and partly so in ether and alcohol. It is volatile to a certain degree. It is rich in sulphur, containing about fifteen per cent. in a condition of such intimate union that it cannot be separated without complete decomposition of the substance.

Dr. Unna, who first recommended it as an important application in skin diseases, found that when it is constantly applied to the healthy skin for weeks, and even inclosed by an impermeable covering, it does not produce dermatitis, which would inevitably follow the application, under like conditions, of an ointment containing ten per cent. of sulphur (*Pharmaceutical Record*, May 15, 1885). According to the physiological experiments of Professors Baumann and Schotten, it produces no toxic effects in dogs in less than two drachm doses, while in doses from three to five drachms it brings on copious intestinal discharges. Professor Nussbaum took as much as seventy-five grains himself, without experiencing the least inconvenience. Little is therefore known of its physiological action, and a more thorough and intimate study of the drug in this direction is much desired.

My attention was first seriously called to this substance by the very practical paper on Ichthyol in Surgery, read by Dr. Edward Martin before the Philadelphia County Medical Society last winter, in which he sums up his own study of the action of the drug, externally applied, in cervical adenitis, in inflammatory indurations of the subcutaneous tissue, in furuncles, in cellulitis and in erysipelas, and, with a few exceptions, he renders a very favorable verdict concerning its influence in these diseases. Testimony of a similar character comes from Professor Nussbaum, who recommends it very highly, both internally and externally, in gout, in rheumatism, in hyperæmia of the fauces, of the larynx, of the pharynx, in neuralgia, etc. The latter authority believes that it is in virtue of its power to constrict the capillary bloodvessels that ichthyol reduces congestions and inflammatory swellings of the cutaneous and mucous surfaces; and the surprising rapidity with which it disperses local hyperemias, as it does erythema of the nose, eczema of the face, for example, which often disappear after a few applications, is evidence that it possesses a marked influence on these structures.

These considerations have led me to its internal employment in the various inflammatory phases of bronchial and pulmonary diseases, especially in those which are characterized by severe cough, copious expectoration, dyspnœa, etc. At first I administered it by the mouth alone, then conjointly with inhala-

tion, but, latterly, I have used it almost exclusively by inhalation, believing that in most cases the best results are obtained in this way. By the mouth I give it every four hours, in capsules, each containing from four to six grains, and for inhalation I employ a 25 per cent. watery solution, and allow the patient to breathe it through a Genois' respirator four or five times a day, about one hour each time. It is sufficiently volatile practically to saturate the air which the patient breathes in this manner. Although it seems to have a disagreeable odor, patients do not, as a rule, object to its inhalation; some even prefer it to carbolic acid.

Its good effects are generally manifested in a lessening of the cough, in diminishing the amount of expectoration, in a relief to the dyspnœa and in an improvement of the appetite. Associated with this amelioration of the symptoms there is usually an improvement in the physical signs—the moist râles disappear, showing that the catarrhal proliferation in the bronchial tubes is checked. The dyspnœa which is relieved by ichthyol is not that which is mitigated by nitroglycerin, stramonium or lobelia and which exists in virtue of a spasmodic condition of the bronchi; but it is that which depends on an accumulation or on an undue secretion of catarrhal material in the tubular parts of the lungs.

Ichthyol is not recommended here as a panacea in all kinds of chest affections, but when it is properly adapted to the morbid conditions, that is, when it is given for profuse expectoration, as in chronic bronchitis, bronchorrhœa, pulmonary consumption, secreting cavities, etc., I believe it to be a positive addition to the therapeutics of pulmonary diseases.

I will append the clinical history of some cases in the chest service of the Philadelphia Polyclinic, in the Chest and Throat Dispensary and in my private practice which have been treated with it.

Case I.—Male, aged thirty-four, was first seen March 20, 1888, when he had a cough and copious yellow expectoration, which had existed for four years. He also suffered from dyspnœa, night sweats, insomnia, had hemoptysis and gives a venereal history. Physical examination showed a small cavity and some mucous râles at right apex. On account of the venereal taint he was placed on eight grains of potassium iodide every four hours

March 24. No better, cough and expectoration same. No change in the treatment.

27th. No improvement. Ichthyol by the mouth, four grains every three hours.

29th. Cough and expectoration much diminished, and thinks he is better in every way. Is now able to sleep. After this date the patient returned to work, from which he had been absent for some time, and has continued to improve ever since. He is still under occasional observation, and there is no doubt that the ichthyol was of much service to him.

Case II.—February 16, 1888. Male, forty-two years old, stone-cutter, had cough and profuse expectoration ever since 1881, when he had pneumonia. He is losing flesh, has much dyspnœa, especially on exertion, and eats well. Physical examination shows a large cavity at right apex. Four grains of ichthyol every three hours were prescribed for him, and a general amelioration of all his unfavorable symptoms took place. He resumed work a short time since.

Case III.—February 8, 1888. Male, aged twenty-six, had hemoptysis, some cough and expectoration, swollen vocal bands, and was very hoarse. Dulness at left apex, associated with crepitation. Was treated with indifferent results until the 9th of March, when he received four grains of ichthyol every four hours, and he has gradually improved ever since so far as the symptoms of his case are concerned.

Case IV.—March 9, 1888. Female, forty-two years old. This is a case of chronic phthisis with quite a large cavity at the left apex, associated with a harassing cough, free expectoration and sleeplessness. She was treated with various palliatives until March 27th, without much relief, when she received four grains of ichthyol every three hours, which gave her more ease than anything else. More recently the inhalation of ichthyol has been substituted for its administration by the mouth, and she says she can readily control the paroxysm of cough by inhaling it.

Case V.—March 27, 1888. Male, aged twenty-three, has coughed for some time, yellow expectoration, no hemoptysis, dyspnœa, appetite poor, night sweats, losing flesh. Weight one year ago one hundred and thirty-eight pounds, now weighs one hundred and twenty-two pounds. His father, mother and one sister died of pulmonary consumption. Physical signs: tympanitic resonance at right apex, extending to second intercostal space, and dulness from there down to base. Dulness also extends from apex to base posteriorly, associated with crepitation and subcrepitation over whole lung. Afternoon temperature $102\frac{3}{5}$° F.

March 31. Temp. 103°. Four grains of antifebrin every three hours.

April 3. Cough less; temp. 101°; same treatment.

5th. Appetite better; added four grains of ichthyol every four hours to the other treatment.

6th. Feels about the same; temp. 104°. Six grains of antifebrin every three hours and same amount of ichthyol.

9th. Temp. 104°. Seven and a half grains of antipyrin every four hours.

16th. Temp. 103°; same treatment.

23d. Temp. 104°. I now gave him a twenty-five per cent. aqueous solution of ichthyol to inhale in respirator in connection with the same dose of antipyrin.

30th. Temp. 102°; same treatment.

May 7. Temp. 100°; cough and expectoration much less, and appetite and general strength much improved; same treatment.

28th. Coughs and expectorates very little and only in the morning; appetite very good; temp. 101°. P. M. Dulness at anterior portion of right lung disappeared, and has diminished behind. No moist

râles audible anywhere, except a few over the site of the cavity; but a slight crepitation at base of same lung in front.

31st. The antipyrin producing an itching rash, it has been discontinued since the 27th inst., and he only inhaled the ichthyol. Temp., 3 P.M., 99¼°.

Case VI.—April 7, 1888. Male, aged eighteen, cough for eight months, expectoration profuse and yellow in color, sometimes blood-streaked, dyspnœa, losing flesh, night sweats, temp. 100⅘°, in the afternoon. Physical signs: dulness over left lung, especially marked behind, associated with subcrepitation. Exaggerated respiration over whole of right lung. Antifebrin four grains every three hours.

April 16. Temp. 99½°; same treatment.

26th. Temp. 100½°: ordered a twenty per cent. solution of ichthyol in water for inhalation, additionally to the antifebrin.

May 3. Temp. 100°. Says his cough and expectoration are improved, and that he breathes easier after each inhalation. Same treatment.

31st. Temp. 100°. Feels very good; continued the ichthyol inhalation, but substituted antipyrin (seven and a half grains) for the antifebrin.

Case VII.—This case has been under my care since October, 1887. He was then fifty-three years old and had a troublesome cough, a profuse, tough, gray expectoration, hemoptysis, wasting, night sweats; and the physical signs showed that the upper portion of the right lung was in process of infiltration. After the hemoptysis had been subdued, the constant cough and the excessive expectoration remained as disturbing factors which nothing succeeded in checking until I gave him the ichthyol inhalations.

This case is a curiosity on account of the many agents which I had given him for the relief of his cough, without any decided, permanent benefit. He had received potassium iodide, calcium chloride, mercury, geranium, euphorbia pilulifera, nux vomica, capsicum, chloroform, ether, tar, tolu, menthol, arsenic, ichthyol by the mouth, atropia, hypophosphites, quebracho, both the alkaloid quebrachine and the fluid extract, carbolic acid by the mouth and by inhalation, codeia, camphor, whiskey and cod-liver oil. Unquestionably these agents proved to be of some service, but not one or any combination of them had the same definite influence in controlling the cough and expectoration as the ichthyol had when I gave it to him in the form of inhalation. Both disappeared almost entirely within twenty-four hours after using it, and neither has returned up to the present time. It must also be stated that on account of a slight rise in his temperature he also received antipyrin during the time the ichthyol was employed, to which must be ascribed some of the beneficial effects.

This line of practice, associated with the giving of antipyrin, antifebrin or phenacetin, has been followed in every case which showed a similar disturbance of temperature, and additionally a most liberal nutritious diet was prescribed, together with such pulmonary gymnastics as seemed advisable.

It is our common experience that cough and expectoration in many forms of chronic chest troubles, especially in phthisis, are two of the most aggravating factors with which we have to deal, and the favorable results obtained from ichthyol in these, as well as in a number of other cases in which it has been tested, recommends it at least for the alleviation of these symptoms and probably also for the amelioration of the local physical conditions which have been witnessed in several instances.

Whether ichthyol, by acting on the capillary bloodvessels, checks the inflammatory changes in the lungs, or whether, by means of its large percentage of sulphur, it merely disinfects the bronchial tubes and in this way inhibits the catarrhal processes, or whether it acts in some other manner are questions which must be left open for future investigation.

CASE OF CHRONIC ATROPHIC ASCENDING PARALYSIS, WITH SCLEROSIS OF POSTERIOR ROOT ZONES.

By HERMON C. GORDINIER, M.D.,
of Troy, N. Y.

May 5, 1887. Mrs. B., æt. forty-five years. Mother died of phthisis; father, of hemiplegia; brother, of some form of paralysis: has a sister, who several years ago had hemiplegia and has since developed epileptic fits, with distinct aura. Patient has had no previous acute illness since childhood. Denies syphilis. Has had eleven miscarriages. Present sickness began eighteen months ago. Patient noticed that on physical exertion she became excessively tired and felt very weak and exhausted; soon after, was compelled to give up all work about her house. At the same time, muscular twitchings began in the right leg; the leg became weak and dragged, and, in order to walk, she had to push a chair before her, or to use two sticks; locomotion soon became so difficult that she was obliged to take to bed or sick-chair. The muscular twitchings annoy her very much and are confined to the muscles of the calf and thigh of the right side, which are wasting rapidly. Muscular twitchings are seen in the right forearm and arm: muscles of hand are atrophied. Bladder and rectum normal.

Physical examination.—Patient much emaciated; face pale; hearing acute; smell and taste normal. No strabismus. Muscles of legs markedly atrophied; no fibrillary twitchings to be seen in the muscles of the lower extremities. The interossei and thenar muscles of right hand wasted. The normal fulness of thenar eminence much flattened; base of first metacarpal bone very prominent; no abduction of index finger; marked depressions between the metacarpal bones, due to wasting of lumbricales. Extensor muscles of hand rapidly wasting; fibrillation distinct in the muscles of the right upper extremity; hand in *main-en-griffe* position. Muscular twitchings beginning in left hand. Rapid atrophy of

interossei and muscles of the ball of the thumb. Irritability of the muscles exaggerated. Reflexes: patellar tendon reflex on right side absent, slight on the left; no foot or rectus clonus; triceps reflex normal. Pupils react to light and accommodation; pupils equal; no change in the disks. Temperature, tactile, painful and muscular senses normal. Grip of hands weak. Extremities cold and little cyanotic.

Electrical examination.—Reaction of degeneration present in the muscles of the lower extremities; they do not respond to the strongest faradic current. The only muscles that do respond in right upper extremity are a few flexors, and the supinators, biceps and deltoid give a sluggish response. Muscles of left hand and forearm respond but slowly to moderate currents. Biceps and deltoid give quick contractions. There are no symptoms of bulbar paralysis, no atrophy of intercostal muscles, no dyspnœa, no headaches. Lungs emphysematous. Heart normal. Urine contains neither albumin nor casts.

16th. Fibrillation has extended to pectoral, rhomboidei, supra- and infra-spinati and lower part of trapezii; has slight dyspnœa; is very weak; tires easily.

June 19. Muscles of back wasting quite rapidly. Bulbar symptoms first noticed; considerable difficulty in swallowing; marked dyspnœa, choking sensations, inability to cough or raise mucus collecting in larynx; changed voice.

27th. Bulbar symptoms progressing; dyspnœa and difficult deglutition very annoying; patient has had no pain or sensory disturbance; no change in sensation.

July 22. Patient very weak. Muscles of left forearm much atrophied; hand in the bird-claw position; muscles do not respond to the strongest faradic currents. Respiration mostly costal; slight nystagmus; marked lordosis; back muscles much wasted, and fibrillation very marked. The normal appearance of the face presents a striking contrast to the rest of the body, which looks like a living skeleton covered with integument.

August 1. Patient died, probably of paralysis of diaphragm.

Autopsy twelve hours after death.—The entire cord and a portion of the brachial plexus were removed; there were no macroscopic changes in the dura or pia mater, and sections of the cord showed no change to the naked eye. The specimens were hardened in a four per cent. solution of bichromate of ammonium. The specimens, after being properly hardened, were sent to Prof. M. Allen Starr, of New York, who kindly furnished me with mounted specimens and made the microscopic examination, which showed the following changes:

(1) In the entire extent of the gray matter of the cord there was a very marked absence of the ganglion cells in the anterior horns. In the cervical segments, where from forty to sixty cells are constantly found in each anterior horn, the number was reduced to six, eight or ten, and in some sections no cells at all were to be seen. Here and there single cells were found in process of degeneration, being swollen and the nucleus absent, or granular, or in a state of fatty degeneration and shrunken; numerous nuclei throughout the gray matter indicated the previous existence of cells which had undergone degeneration. No groups of cells had escaped in the process of degeneration. There was an increase in the neuroglia nuclei throughout the gray matter. There was a very marked increase in the size and apparent number of capillaries throughout the gray matter, both in the anterior and posterior horns.

(2) The appearance of the white matter at different levels. In the cervical region there was a slight increase in the connective tissue trabeculæ throughout the part of the antero-lateral columns lying adjacent to the gray anterior horns; but this was not limited in extent to any functional tract, and there was no evidence of systematic lateral sclerosis. The nerve-fibres were somewhat crowded, but apparently not destroyed by the connective tissue increase.

(3) In the sacral, lumbar and lower dorsal regions of the cord, as high as the seventh dorsal segment, there was a very distinct *sclerosis* of the *posterior root zone*, more marked on the right than on the left side. This was more extensive in the sacral than in the lumbar, and in the lumbar than in the dorsal regions; but in the sacral and lower dorsal segments the posterior median column was not affected at all by this sclerotic change; and throughout all the segments the zone immediately adjacent to the posterior gray horn at its periphery and the area lying on the border of the columns of Goll and Burdach were not affected. The anterior nerve-roots were degenerated, and the cross section of nerves of the brachial plexus showed deficiency of fibres in comparison with normal nerves.

A case is reported by Ross, vol. i. p. 923, with almost the exact anatomical distribution of the lesions as in my case.

INSUFFICIENCY OF THE INTERNAL RECTI MUSCLES.[1]

By H. F. HANSELL, M.D.,
CHIEF OF OPHTHALMIC CLINIC OF JEFFERSON MEDICAL COLLEGE HOSPITAL, ETC.

THE attention of the profession has been frequently called, in the past few years, to the important *rôle* played by refractive errors in the causation of neurotic symptoms, and it is a well-known fact that headaches of years' duration have been cured by wearing the proper correction of an optical defect. This knowledge is not confined to the profession, but is well known to the laity, and the sufferer from chronic headache does not wait until he has vainly exhausted the pharmacopœia, but seeks at once the relief offered by glasses, provided he has reason to connect his sufferings with the use of his eyes.

The defects of refraction are hypermetropia, myopia and astigmatism, simple and compound. Each causes eye-strain and headache, which can be relieved by wearing a concave, convex or cylindrical glass of the correct curvature, singly or in combination. Most

[1] Read before the Pennsylvania State Medical Society, June, 1883.

cases of functional headache which come under the notice of the ophthalmic surgeon may be classified under two heads: 1st. Those due to accommodative strain depending upon some error of refraction. 2d. Those due to an insufficiency of one or more of the extrinsic muscles. The causation of the first class is well understood and the treatment eminently satisfactory. To the second class I wish to invite your attention in this brief paper.

The diagnosis of insufficiency is attended with many difficulties, and thus far no accurate instruments or methods have been devised which at one examination can detect, with any degree of certainty, a want of coördinative action on the part of the recti muscles. The simplest and most reliable method for distance is by the use of prisms and the candle or small gas flame, and for near by, prisms and a modification of the Gräfe test.

In testing for errors of refraction 20′ is considered infinity—that is, rays of light coming from an object of small size at that distance are practically parallel and focussed by the emmetropic eye on the retina with no effort of accommodation, and so each eyeball is in a position of rest and its axis parallel to that of the other, and an object seen at 20′ distance makes an image on corresponding parts of each retina and is seen single. The extrinsic muscles are seen relaxed, and if they are in equilibrium the lines of vision running from the fovea of each retina meet on the object at 20′, forming a very acute angle; this angle is, however, not regarded, and these lines are said to be parallel. Now, if for any reason one eye is diverted, the rays of light from the object will not fall on the fovea but on a neighboring part of the retina and double images will be seen. If these images are in the same horizontal plane, the deflection will be caused by a want of equilibrium between the external and internal recti muscles; if in the same vertical plane, by that of the superior or inferior rectus. When the image seen by the right eye is to the right of that seen by the left, homonymous diplopia results: the equilibrium is disturbed, the eyes are converged, the external recti are relaxed and the internal contracted; and if it is to the left, crossed diplopia, the opposite condition, obtains.

These laws hold for testing at the near point or reading distance. Here Gräfe's test, which consists of a dot with a line running through it vertically, is usually employed. Practically this test is more exact if the dot without the line is used, as suggested by Prof. Wm. Thomson, for when there is a tendency to double vision and the insufficiency is not easily discovered, the line stimulates the brain to preserve the equilibrium. When an insufficiency of high degree exists the patient will complain of double vision both for far and near, and the degree of deflection can be readily ascertained by the above methods; but when the insufficiency is only suspected, and no complaint is made of double vision, the tests must be modified by the induction of vertical diplopia by means of a prism.

For obvious reasons the brain refuses to recognize double images, when by muscular effort it can control it. A patient with even a decided insufficiency of the muscles either side will maintain that he sees but a single object, as he really does, because he has enough power to hold his lines of vision parallel for distance or converged for near. If, however, a prism strong enough to overcome the superior or inferior rectus be placed vertically before either eye he will have vertical diplopia. Now, if the side muscles are in equilibrium in testing for distance, one light will be directly over the other, or, for near, the two dots will be in a vertical line; but when the internal muscles are too weak and the lines of vision diverge, the patient will have crossed diplopia, and, if the external muscles are too weak, homonymous diplopia. The prism placed horizontally, which is necessary to bring the light or dot back to the vertical line, will be the measure of the insufficiency.

Effects of refraction. Latent divergence is more common than is supposed. It is most frequent in myopia, but is not uncommon in hypermetropia and emmetropia and is more constant with myopia than latent convergence with hypermetropia. This is due to the relation of accommodation and convergence. When an emmetrope fixes a small object at 14″ distance with both eyes, he uses just as much contraction of the internal recti as will bring the centre of each retina opposite that object. If we cover one eye, the direct stimulus of the convergence is removed, and if, in spite of that, the lines of vision do not diverge, the effort is maintained by the accommodation, which is associated with the convergence. When a myope of one-eighth, for instance, fixes an object 12″ distant, the accommodation is not brought into use, and that stimulus is removed from the convergence. Hence, if one eye is excluded, he has so much the less stimulation than the emmetrope, and the anatomical position of the eye's parallelism is the more readily assumed. A correction of the myopia, restoring the case to one of emmetropia and thus forcing the accommodation, which in turn necessitates convergence, may cure an insufficiency which may be present in an uncorrected case.

The *symptoms* are not dissimilar to those caused by errors in refraction, especially hypermetropia and astigmatism. Reading and the near use of the eyes are possible for only a short time. They give rise to neuralgia, dizziness and nausea, blepharospasm and then, perhaps suddenly, double vision, with the lines and letters running together. The muscles are able to endure the strain of convergence for a limited time, before one eye diverges. Some cases can continue to work for years, by learning to tilt the head in the direction of the affected muscle, while others

are compelled to forego all close application. A cessation of pain and headache occurs at once when vision ceases to be binocular; one eye diverges and the work is done by the other. The case has now become one of relative latent divergence—that is, binocular for distance, monocular for near and, finally, passes into manifest, absolute external strabismus.

The *causes* of insufficiency are not readily determined, but, in general, they may be divided into constitutional and local. The first, which may underlie all cases and predispose to the affection, are so-called malaria, neuropathic predisposition. "Difficulties attending functions of accommodating and adjusting the eyes in the act of vision, or irritation arising from the nerves involved in these processes, are among the most prolific sources of nervous disturbances and more frequently than other conditions constitute a neuropathic tendency" (Stevens's *Functional Nervous Diseases*), exhaustion from overwork or confinement, convalescence from slow fevers, muscular debility, etc. The main local causes are errors of refraction; others are the use of one eye armed with a magnifying-glass in fine work, as watchmaking, long-continued reading, writing and other close application in bad light, etc.

Treatment. The problem in the treatment is to know when the symptoms can be relieved by the prisms, and when, without the preliminary use of prisms, an operation should be advised. Here, as in other domains of surgery, the conservative plan should be followed, both for the general reason that operations are the last resort, and the part is more or less changed from the normal in its anatomy and functions, and for the especial one that in cases which seem at the first examination to be fit for a division of the muscle, the internal rectus not infrequently regains its normal strength in the improved general condition of the patient. Whether the prisms will effect relief or cure depends upon the degree of the insufficiency and the relative strength of the muscles, which in all cases should be ascertained by their power of overcoming prisms. Normally the internal are immensely more powerful than the external, and are able to fuse images through prisms of 50° to 100°, while the limit of the external is reached at 12° to 15°. If the insufficiency is not in excess of 10°, prisms of one-half that strength divided between the two eyes—3° in one, 2° in the other—should be ordered.

In selecting the eye which is to wear the stronger prism, difficulties arise, for insufficiency is seldom the fault of one internal muscle more than the other, but it is in the coördination of both. When double vision is induced by vertical diplopia the patient not infrequently designates the image which is displaced by the prism as the true one. The eye before which the prism is placed sees no displacement, but the object seen by the other eye is the one which seems to have been moved. Insufficiency is primarily a nervous affection, muscular only in its symptoms and manifestations, and the misinterpretation as to the displaced dot must be purely psychical. While the actual displacement when a vertical prism is before the right eye is certainly the image seen by that eye, the brain refuses to recognize it as such, but transfers the displacement to the left, the image seen by which has not been disturbed. In such cases it is impossible to conceive that the insufficiency is in the right or in left internal rectus alone, but must be in the combined action of both—that is, the converging power is too weak for the work required of it. The external recti are not in every case, indeed, not in many cases, stronger than the normal, and not infrequently they are weaker. The act of convergence is not in itself an antagonism between the internal and external muscles, but is an act of the internal alone, as stimulated by the third nerve. If the prism required to bring the dots in a vertical line be over 10° for far and 15° for near, little help can be expected from the wearing of prisms, for the insufficiency is great enough to produce double images. Diplopia for far and near will be a prominent symptom, in the distance, when looking at a single well-defined object, such as the moon, and near, looking at a needle or other bright, small object.

Dr. George T. Stevens, who has contributed largely to the literature of the insufficiency of the ocular muscles, introduces a nomenclature, the main advantage of which is to designate the affection in one word, and by the prefix of that word name the variety. Thus "heterophoria" (*ekros*, deficient; *phoros*, a tending) is the general word for insufficiency of all varieties. This is modified according to the muscle affected: esophoria, a tending of the visual line inward; exophoria, a tending of the visual line outward; hyperphoria, right and left, a tending of the right and left visual line above its fellow. Tendencies in oblique directions may be expressed by a combination of the specific terms.

The following cases, briefly described, have been selected to illustrate the principal symptoms and the principles of treatment.

Case I.—Miss A., æt. nineteen, an industrious student, who uses her eyes many hours daily in close work, had been for some time, and still is, under treatment for neurasthenia, complained of nearly constant headache and pain in the eyes, unrelieved by a correction of her astigmatism, which she had worn for some years. Insufficiency of internal rectus 2° for distance, 5° for near. Ordered 2° O. U. to be worn over astigmatic correction in reading. Returned in a month with inability of binocular vision for near. Her power of convergence was nearly lost, though she suffered less pain and headache. Tenotomy advised and declined. Returned in a year intensely annoyed with constant double vision. In-

sufficiency for near varied from 15° to 20°. Tenotomy of right external rectus. In a month the symptoms had disappeared.

Case II.—Mr. G., æt. thirty-five years, suffered for years with asthenopia. Had refraction tested several times, and had worn a correction for a very slight H. without relief. Insufficiency 5° far, 10° near; ordered 3° base in O. U. for near. Returned in five weeks, saying he could use his eyes for three hours with the prisms without pain, under the same conditions under which he had formerly been able to read but five minutes. The insufficiency was unchanged.

Case III.—Mr. C., æt. twenty-two; suffered from headache for years. Was obliged to give up his college course on account of his asthenopia. Had a moderate degree of M. and As. which had been corrected years before. Insufficiency = far 3°, near 6°. Ordered 2° base in O. U. In one month, could read two hours before headache appeared. In two months, headache entirely gone. In six months, no insufficiency for far or near, and could read all day without pain or prisms.

Conclusions:

1. In all cases of continued functional headache the extrinsic muscles should be examined.

2. Insufficiency is found in E., H., M. and As.

3. Headache due to insufficiency can be relieved by prisms or by tenotomy; by the former if less than 10°; by the latter if more than 10°. In my experience an operation on both eyes has never been necessary.

TREATMENT OF HYDROCELE BY INCISION OF THE TUNICA VAGINALIS AND BY A NEW PROCEDURE.

By W. F. McNUTT, M.D., M R.C.P. Ed.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE IN THE UNIVERSITY OF CALIFORNIA, CONSULTING SURGEON AND PHYSICIAN TO ST. MARY'S HOSPITAL, ETC.

In The Medical News of April 7, 1888, my old friend, Dr. W. W. Keen, of Philadelphia, contributes an article on the "Radical Cure of Hydrocele by Excision of the Tunica Vaginalis," the article having been read at the Philadelphia Academy of Surgery, March 5, 1888. In the discussion which followed the reading of the paper (as reported in The Medical News), Dr. Gross, of Philadelphia, begged leave to correct Dr. Keen in regard to the history of the operation and says:

"The history of the operation is briefly as follows: In 1873, Volkmann resorted to incision of the tunica vaginalis, with drainage and suture of the edges of the tunica vaginalis to the edges of the scrotum. In 1875 he incised the tunica vaginalis, united it with sutures, and also passed deep sutures, bringing the surfaces of the tunica vaginalis together. He was, therefore, the first to excise, as he was the first to incise, etc."

During the discussion Dr. Keen also makes use of the expression "the incision of Volkmann." From this language I have no doubt that Volkmann was the first to announce or report the incision of the tunica vaginalis as a remedial measure for the cure of hydrocele. He was not, however, by any means, the first to practise it.

I commenced the study of medicine, in 1859, with Dr. Samuel Muir, of Nova Scotia, who enjoyed a very extensive surgical practice, being well and favorably known throughout the lower provinces. Shortly after I commenced my studies, a patient came into his office with hydrocele. Dr. Muir remarked that this was a case of hydrocele upon which he had already operated three or four times by tapping and injections of diluted tincture of iodine, and that, having failed to make a cure, he would now proceed to make a free incision, laying open the sac, which he would brush with pure tincture of iodine, also saying that this was the proper treatment in all such cases in which the injection failed to cure or in which the injection was followed by suppuration. As he said nothing about the procedure being new or original with him, my attention was never called to the literature of this operation until I read Dr. Gross's statement.

I have treated, in all, quite a number of cases of hydrocele and have found it necessary to follow my old preceptor's method on two occasions. The first case was that of a French marketman, age about forty, who consulted me in 1869; he had been operated on by tapping and injections several times, and a great deal of inflammation and pain had followed the last injection, about three months before. The hydrocele was large and the scrotum thickened and infiltrated; he was unwilling to have the operation repeated, on account of its frequent failures and the pain and inflammation caused by the last. I made a free incision and brushed the tunic with tincture of iodine; the result was a perfect cure. I saw the man a few years ago; he remained well. The second case on which I operated by free incision was for inflammation and suppuration which followed aspiration and injection.

Recently I have adopted a new and, so far as I know, an entirely original method of treating hydrocele, viz., to puncture the sac with Southay's dropsy trocar, leaving the canula in; after the fluid is all discharged applying absorbent cotton, covering with oiled silk and retaining with a suspensory bandage. As yet I have only aspirated four times: one case was cured, the canula remained in ten or twelve days, there being a few drops of pus in and about the canula. One case disappeared, canula and all; in one case the canula worried the patient and I removed it; and in the fourth case the canula dropped out. In both the latter cases the fluid reappeared, and I have repeated the operation since with the small canula, not leaving it in, but simply to relieve the patient. They both objected to injections.

I have had a canula made by Folkers Brothers, a quarter of an inch longer and with a double bulb. In operating I intended to force the first bulb through the scrotum into the sac, so that it will remain there until it is removed. I attempted to tie the little Southay canula in but failed.

Any one familiar with Southay's dropsy trocars will readily understand what is meant by a double bulb, as each little canula has a bulb on its distal end to prevent it from passing through the skin and being buried in the cellular tissue. The object of leaving the canula *in situ* is to drain off the fluid as it accumulates, thus allowing the surfaces of the sac to remain in contact, when it is expected that they will soon adhere, effecting a radical cure. It is probable that in most cases adhesions would take place after tapping were it not for the reaccumulation of the fluid separating the membranes.

ANOTHER CASE OF EPILEPTIFORM CONVULSIONS FOLLOWING THE USE OF COCAINE AS AN URETHRAL ANÆSTHETIC.

By J. CLARK STEWART, M.D.,
of Minneapolis, Minn.

Reading in The Medical News of July 21, 1888, the account of a case of death following injection of the urethra with a solution of cocaine, I am led to narrate a case occurring in my own practice, which resembles that reported, though, fortunately, without a fatal result.

A. B., æt. thirty-two, English, came to me for gleet, and on examination of his urethra I found a stricture four and a half inches from the meatus admitting No. 18 F. There were also several slighter constrictions anterior to this, and the meatus admitted only No. 22 F.

There was no reaction after the examination, and one week later I injected the urethra with ʒjss of a four per cent. solution of cocaine hydrochlorate, and proceeded with an Otis dilating urethrotome to cut meatus and anterior strictures and dilate canal quite thoroughly.

I then passed a steel sound, No. 30 F., to the neck of bladder only, and after removing it, patient sat up. He almost immediately said "I feel sick," stiffened out and became unconscious, with widely dilated pupils and rapid and feeble pulse. This condition lasted, perhaps, one minute, when he recovered his senses, though very much dazed, and said, "What is the matter; I feel very queer?"

Then, after a moment or two, he said "I feel badly again," and sank back on the table and became unconscious. He again became perfectly rigid, but this time went on to have violent general convulsions, almost throwing himself from the table. The convulsions were clonic, beginning in face and extending over the whole body, and there was, throughout, partial suspension of respiration and increasing rapidity and weakness of the heart's action. The convulsion lasted, perhaps, two or three minutes, and the patient became deeply cyanosed and then very gradually recovered consciousness, it being about an hour before he was able to leave the office, though there was no repetition of the convulsion.

I saw him repeatedly afterward, and dilated his urethra with the Otis and steel sounds without cocaine and without any disagreeable symptoms, though my having put him on bromide of soda, gr. xxx, t. i. d., may have influenced this.

After closely questioning him I obtained an obscure history of epilepsy showing itself as *petit mal* and concluded that I had to deal with a simple case of epilepsy, and that the convulsion had been caused by the excitement of the operation, perhaps influenced by some specific action of the cocaine.

Reading the report of Dr. Simes's case, I am led to record mine, thinking it may prove of interest from the similarity of symptoms, and from the fact that a history of previous non-convulsive epilepsy was elicited.

In closing, I should like to suggest as a query, to our neurologists, whether cocaine may not have some specific action in precipitating the epileptic attack in predisposed subjects.

328 Nicollet Ave, Minneapolis, Minn.

MEDICAL PROGRESS.

Some Indications for the Administration of Chloral and of Morphine.—Both choral and morphine have peculiar uses. The one will not always replace the other. Aufrecht, of Magdeburg (*Therap. Monatsh.*), recommends chloral, exclusively, for delirium tremens; he has so used it in several hundred cases. He expresses surprise that opium or morphine should yet be used in this condition. It is only since the introduction of chloral that a successful treatment of delirium tremens has been possible. The drug, however, is not to be given in broken doses. Single doses of forty-five or sixty grains in six drachms of syrup and water, several nights consecutively, furnish the best results. The author has found this dosage exceedingly well borne by adults; smaller doses do not answer. He urgently warns against the addition of morphine to chloral; he considers the combination dangerous. He has also had good results from the use of chloral in the eclampsia of pregnancy. If it can be administered, chloral is preferable to morphine in maniacal conditions. In a case of singultus which had persisted for twelve hours, the administration of morphine internally failed of result. After forty-five grains of chloral had been given, the patient slept throughout the night. The following morning, shortly after awaking, the hiccough recommenced. Forty-five grains of chloral were again administered, and, after a sleep of several hours, the trouble disappeared. Not less to be recommended is the use of chloral in the sleeplessness of elderly persons, probably dependent upon beginning atheroma of the cerebral vessels. Small doses, about seven and one-half grains, are advised in the beginning.

The range of usefulness of morphine is more extended. To attain the best results the question of administration by the mouth, or subcutaneously, must be considered.

For the relief of pain, the result of irritation of serous membranes, morphine is only to be used subcutaneously. In the same way, the subcutaneous administration is to be preferred to internal administration in cases of convulsive and painful contractions of canals or cavities, the walls of which are usually composed of unstriated muscular fibre, be it uterus, gall-bladder or intestine. Especially in cases of severe gall-stone colic, should the suffering of the patient not be prolonged by giving morphine by the mouth, but the subcutaneous injection be immediately made. This method is also to be exclusively recommended in all neuralgias, whether severe sciaticas or trigeminal neuralgias or the lancinating pains of tabes. The author finally observes that in melancholia morphine, subcutaneously, affords rest and sleep, while chloral does not seem indicated. Thus, morphine is to be administered in melancholia, chloral in mania. For adults the dose is gr. ⅙ to gr. ¼. In cases of severe gall-stone colic and of melancholia, as much as gr. ⅓ has been used at the first injection. A not inconsiderable range of application belongs to morphine given by the mouth. This method is to be recommended in disorders of the mucous membrane, whether of the air-passages or of the intestinal canal. To relieve the cough of simple bronchial catarrh, as well as that of affections of the pulmonary parenchyma, morphine given internally has proved useful. It occupies the first place in case of gastric ulcer with much pain; in cases of diarrhœa, it gives as good results as opium; it is given with good results in dysentery, without the preceding administration of castor oil, until the tenesmus is relieved and the number of stools diminished. In the worst cases, gr. ¼, two or three times a day, will be sufficient.

The author recommends, in the cases of patients with convulsions and who are unconscious, particularly in the eclampsia of pregnancy, that forty-five grains of chloral in six drachms of water and syrup, be administered through a soft flexible œsophageal tube introduced through the nose. Better results are thus obtained than by injection into the rectum, as in the latter a portion of the injected fluid readily and frequently escapes.—*Memorabilien*, July 6, 1888; from *Centralblatt für die gesammte Therapie*, 1888.

On Sudden Death in Infants.—Dr. P. Grawitz, of Greifswald, records two cases in a recent number of the *Deutsch. med. Wochensch.* One child was eight months old, the other six months. The usual signs of death by suffocation were found *post-mortem*, and, in addition, a very large thymus gland in each case. It was satisfactorily proved in one case that the child was not suffocated; the other case was somewhat doubtful, and it was also shown that the children enjoyed perfect health up to a few minutes before death, which was preceded by sudden dyspnœa and cyanosis. Virchow, in his work on tumors, states that he possesses a preparation of an enlarged thymus, from a child who had died of asthma. "The thymus was so enlarged," says Virchow, "that I do not see how any one can deny that the dyspnœa may have arisen from its pressure." Only two such specimens are to be found in the rich collection of the Berlin Pathological Museum, which shows the rarity of this condition, taken alone. The question is of great medico-legal importance—*British Medical Journal*, July 28, 1888.

A Peculiar Reflex Manifestation.—Thomas, of Freiburg (Verslg. d. Südw.-deutsch. Neurologen u. Psychiater), described a peculiar reflex manifestation which he has observed in himself. Moderately strong irritation of the oral mucous membrane gives rise to a sensation of strangury and vesical tenesmus, which occurs even if the bladder is emptied immediately preceding the experiments.—*Wiener medizin. Pr.*, July 1, 1888.

Hot Water in Diseases of the Eye.—Connor (*Centralblatt für prakt. Augenheilkunde*) recommends baths of hot water as an excellent means of treatment in various disorders of the eye—from simple catarrh and phlyctenulæ to scleritis, iritis and hyperæmia of the retina. When, with the instillation of a mydriatic, the pupil fails to dilate sufficiently, hot water aids the action; in catarrhal and purulent ophthalmia, it limits the inflammation; in glaucoma and dacryocystitis, it diminishes pain. There are no contraindications to the use of hot water, which acts with varying efficiency according to the method of application. The author usually has a drinking glass filled with hot water, the patient so inclining the head that the affected eye is immersed. The water remains warm for a considerable period, so that the eye may be bathed for some time without discomfort.

If one so choose, he may add antiseptics to the water. This method has the advantage over poultices that its execution does not require an expert. The local action may be thus tabulated: 1. Contraction of the blood-vessels of the eye and of contiguous structures; the ophthalmoscope shows the retinal vessels contracted after such a hot bath. 2. The hot water washes away deranged secretions and excretions, and destroys the germs contained; the bacillus of anthrax, for instance, is destroyed by a temperature of 96° F.; many eyes can support a higher temperature. 3. The healing activity of the reparative tissue or protoplasm is stimulated. 4. The hot water acts directly upon certain conditions of muscular weakness or spasm.—*Memorabilien*, July 6, 1888; from *Centralblatt für die gesammte Therapie*, 1888.

A New Preserving Fluid.—Dr. T. M. Prudden gives the following formula for a new preserving fluid:

Water	1000 c.c.	(33 fluidounces).
Common salt	100 gm.	(3¼ ounces).
Saltpetre	25 "	(℥vj ℈j).
Carbolic acid	5 "	(77 grains).
Glycerin	15 c.c.	(℥iij ℈ij).
Amylic alcohol	50 "	(1⅔ ounces).
(or Ethylic alcohol	100 ")	(3¼ ounces).

Specimens should be first soaked in a strong brine and then placed in a large quantity of this fluid. He believed the mixture would be found to serve a useful purpose in the temporary preservation of gross pathological specimens, without changing their color or otherwise altering their general appearance. The mucous membranes were particularly well preserved in the fluid.—*Med. Record*, August 4, 1888.

The Use of Sozoiodol in Affections of the Nose and Larynx.—Fritsche, of Berlin, upon the recommendation of Lassar, has used sozoiodol in eighty-eight cases of rhinolaryngeal disease. The results, as given in the *Therap.*

Monatsh. for June, were good. The remedy was used in combination with potassium, sodium, zinc and mercury. The combination with the first two was used of normal strength; that with zinc, of one-fifth to one-tenth; and that with mercury, of one-tenth to one-twentieth. The best results were had in all catarrhal conditions of the mucous membrane of the air-passages, with a tendency to inspissation of the secretion.

In laryngitis sicca and in the dry forms of pharyngeal and naso-pharyngeal catarrh, in which the zinc preparations were used, the cure was complete in acute cases, while in chronic cases marked permanent improvement resulted. The secretion was first liquefied, then diminished. In cases of atrophic nasal catarrh, insufflations of the potassium and zinc preparations caused more marked improvement than other measures; the secretion losing its tenacity and the fetor diminishing. Cases of inveterate ozæna succumbed to the insufflation of the mercurial combination alternating with that of zinc, the local irritation immediately causing a copious, thin secretion, which persisted in greater or less degree, and was followed by disappearance of fetor. In hypertrophic rhinitis and rhinopharyngitis, partly with chronic thickening, the alternate insufflation of the three crystalline combinations proved most successful. With increased secretion the swelling of the mucous membrane grew less, and the erectile tissue contracted, so that respiration became correspondingly freer. The crystalline salts caused a rapid healing of wounds after the use of the galvano-cautery. Tubercular ulceration of the larynx and pharynx rapidly began to clear up and develop healthy granulations, particularly after the use of the zinc salt; complete cicatrization was not noticed, probably on account of the short length of time of treatment. Five cases of nasal and laryngeal syphilis, in part associated with gummatous affections of the velum and of the tongue, were completely cured by insufflations of the mercurial salt, together with mild internal mercurial medication.—*Wiener medizin. Pr.*, July 1, 1888.

Santonin and Santoninoxym.—COPPOLA (*Archiv. pl. Scienze med.*, vol. xi., 1887) shows by experiments upon dogs that santoninoxym, a crystalline substance of similar composition to and a product of santonin, in doses of fifteen grains given internally, does not affect the condition of the animals, while similar doses of santonin are followed by convulsions. The author proved in his own case and in that of others that santoninoxym appeared in the urine four hours after ingestion, while santonin appeared in half an hour. Santonin is thus more readily absorbed than santoninoxym and has slight toxic qualities. The anthelmintic effects of santoninoxym, as shown by clinical investigation, are like those of santonin, and the author believes that the former, constructed by Lanizarro in 1885, will ultimately replace the latter.—*Deutsche medicinische Wochenschrift*, July 12, 1888.

Retention of the Placenta for Seven Weeks.—DR. VARNEK, writing in the *Vrach* on the question of the management of retained placenta, mentions a case which occurred under his charge in the Basman department of the Moscow Artisan Hospital, which he thinks shows that, even when the placenta is found tightly locked up in the uterus several days or weeks after labor, there need be no necessity for recourse to such serious measures as were adopted by Schultze, who in a similar case performed abdominal section and extirpated the uterus. Dr. Varnek's patient was a married woman and had been attended by a midwife, who, after a great deal of very painful intrauterine manipulation, had assured her that she had got the whole of the after-birth away. The patient attempted, after the sixth day, to attend to her household duties. She was, however, very weak, and, as she grew worse and began to suffer from pain in the abdomen and back, she sought, a fortnight after the confinement, admission under Dr. Varnek. She was found to be in a low, weak, anemic state. The abdominal walls were lax. The uterus could be felt as a dense hard mass, extending up to the umbilicus. The external os admitted the finger, but the internal os was much too contracted to permit the cavity to be entered. There was but little discharge, and this was inoffensive. The patient was treated by warm vaginal injections of carbolized water (1 in 50), iodoform suppositories and the internal administration of ergot and ergotine. The condition improved slightly for a time, but in about a month from the time of confinement hemorrhage occurred, the temperature (which had been normal) rose, and shortly afterward the discharge became very offensive. Attempts were then made to examine and clear the uterine cavity. The internal os having somewhat dilated, a partial exploration was made, which revealed the presence of the placenta in a very hard, dense condition, firmly attached to the uterine walls. Persistent efforts, both with the fingers and with a sharp curette, failing to remove it and the patient being much exhausted by the manipulation for which she had been placed on the operating table, she was put back to bed and a prolonged irrigation with a 1 per cent. solution of carbolic acid ordered, a mixture of iodoform and glycerin having been first applied to the interior of the uterus. For the next few days irrigation was practised for from four to ten hours daily, the general condition improving. In a little more than a week a portion of the after-birth came away, which was entirely inoffensive, and the next day the whole of the remainder was got rid of. After this the patient made a rapid and complete recovery. Here the placenta had remained in the uterus fifty days after the confinement, and its ultimate removal is attributed by Dr. Varnek mainly, if not entirely, to persistent and prolonged irrigation.—*Lancet*, July 28, 1888.

Cystisin in Migraine.—From its power to contract the bloodvessels, KRAEPELIN (*Neurolog. Centralbl.*, 1888, No. 1) was led to use cystisin in the angioparalytic form of migraine. One twenty-fourth to one-twelfth of a grain of nitrate of cystisin, injected subcutaneously, particularly if given at the beginning of the attack, in a half hour relieved the redness, the feeling of oppression and the pain; only slight headache remained. Taken internally, it failed entirely; in spastic migraine it increased the pain.—*Centralbl. für klin. Med.*, July 7, 1888.

The Treatment of Bleeding from the Nose.—WADE recommends the expedient of Hutchinson. The hands and feet of the patient are placed in water as hot as can be borne. This will check the most obstinate epistaxis, without any ill consequences.—*Deutsche medizin. Wochenschr.*, July 19.

Gastroliths.—A curious and, as far as is known, unique case of gastrolith is recorded in one of the Dutch journals. A druggist had a circumscribed tumor in the epigastric region, the position of which varied on respiration, and which was tender on pressure. Medicines had no permanent effect upon it. Spleen, liver and kidneys were normal as to position and size. The appetite was very good and the bowels were regular. Vomiting of a small quantity of fluid containing mucus and bile, but almost always free from hydrochloric acid, occasionally took place. Nausea was constant, and it was said that hematemesis took place, but this was not actually observed. Gradual emaciation took place, the look became cachectic, and indolent swelling of the left supra-clavicular and axillary glands was noticed. The patient was examined under an anæsthetic and the stomach washed out, but exploratory incision was steadily refused. The diagnosis, according to the probabilities, was cancer of the stomach. The case ended fatally, and the autopsy showed that the stomach, which was of normal size, contained a concretion having the outline of the organ and almost filling it. At the pyloric end lay two smaller fragments of the size of hen's eggs. The weight of the tumor was 885 grammes (a little over 28 ounces). It had a strong fecal odor, but contained no skatol. No nucleus was present. Microscopic examination showed starch granules, cells containing chlorophyll, bundles of vessels, but nothing to determine the animal origin of the concretion. Chemical analysis showed that it contained 0.56 per cent. of nitrogen. It was observed that with the exception of the formation in Langenbuch's case described in 1884, which contained no hair, all the others observed in the human subject were composed more or less of hair. In the present case, on the other hand, the tumor was identical in constitution with the "food balls" of ruminants, and stood alone.—*Med. Press*, July 18, 1888.

Salicylate of Mercury in Gonorrhœa and Syphilis.—Schadek has tested the usefulness of the salicylate of mercury in gonorrhœa and syphilis. The drug, as used, is an amorphous, white, odorless and tasteless powder, of neutral reaction, with difficulty soluble in water and alcohol, more soluble in glycerin on the addition of soda or common salt, especially if the solution is warm.

He uses the following combination in gonorrhœa:

℞.—Hydrarg. salicylat. . . . gr. iij.
Sodii bicarb. . . . . gr. iij–gr. iv.
Aquæ destill. . . . . f℥ xvij.

In acute cases four or five injections were made daily. Only slight, transient irritation was occasioned. Improvement began after two or three days. Some cases of acute and subacute gonorrhœa were cured in fourteen to twenty-one days; others were not cured at all. The drug is not abortifacient.

In cases of syphilis the remedy was used externally, internally and subcutaneously. The author is reserved as to external use of the drug, as he has not used it sufficiently. Internally it was given in the following manner:

℞.—Hydrarg. salicylat. . . gr. xv.
Ext. et pulv. glycyrrhizæ
q. s. ut ft. pil. no. lx.—M.

Sig.—Three to six pills after meals; never on an empty stomach.

For subcutaneous, or rather intra-muscular, injection, the following suspension was antiseptically used:

℞.—Hydrarg. salicylat. . . gr. vj.
Mucilag. gummi arabic. . ♏ ix.
Aquæ destill. . . . . f℥ iv.

The injections were made at intervals of two or three days; they numbered six to twelve; in one case, however, sixteen were made. The number of cases treated was twelve.

The author summarizes the results as follows: 1. The salicylate of mercury is not less useful as an anti-syphilitic than the other preparations of mercury hitherto used; it is well adapted to the treatment of secondary syphilis; given internally, it causes a rapid disappearance of the milder symptoms and is useful in the after-treatment. Introduced intra-muscularly, the remedy has the power of completely removing the syphilitic symptoms. 2. The drug, unlike other preparations of mercury, causes no unpleasant local complications; in this respect, the salicylate may be considered the best preparation of mercury, because neither by internal administration nor by intra-muscular injection, although insoluble, does it ever give rise to symptoms of local irritation or of constitutional disturbance. 3. The external application of salicylate of mercury is most useful in various forms of syphilitic deposit, causing absorption and cicatrization. 4. It acts favorably in urethritis acuta and subacuta. The secretion of pus speedily diminishes and the other inflammatory symptoms disappear. The remedy is, however, not always efficient.—*Centralblatt für die gesammte Therap.*, July, 1888; from *Monatsh. f. prakt. Dermatol.*, 1888, H. 10.

Salol in the Diagnosis of Gastric Affections.—Dr. Ewald gives some results of experiments on the behavior of salol, performed at his request by Dr. Einhorn. Sivers and himself had shown that when salol was given, the appearance of salicylic acid in the urine was delayed by some agents and accelerated by strychnine and electricity, and that as decomposition of the salol could not take place in the stomach, the variations in the times of its appearance in the urine were due to its earlier or later passage from the stomach into the small intestine. Proof of this was also equivalent to proof that strychnine and electricity hastened the passage of food from the stomach. It had been shown before that when a moderate meal was taken salicylic acid appeared in the urine in from three-quarters to an hour after taking 15 grains of salol. It never appeared in healthy individuals in less than three-quarters of an hour, its appearance was sometimes delayed as long as an hour and a quarter. Dr. Einhorn's experiments showed a steady acceleration of the time of the appearance of the reaction after both faradisation of the epigastric region for ten minutes, and ext. strychninæ $\frac{1}{20}$ grain. Hydrochloric acid generally retarded the appearance of the reaction. It usually appeared more quickly when the stomach was empty or after a single glass of water. Carlsbad salts and bicarbonate of soda had a different effect in different individuals, sometimes retarding and sometimes accelerating the appearance of the reaction.

The bearing of the experiments on the motor functions of the stomach was of importance. Salol when taken during digestion was not absorbed from the stomach,

but from the small intestine, as an alkali was required for its decomposition, before which absorption could not take place. Strychnine and electricity, therefore, hastened the passage of the drug from the stomach into the small intestine. Alkalies had different effects in different persons, for the reason that in some they produced an alkaline condition of the contents of the stomach, and decomposition and absorption of salol took place from the stomach itself, thus causing an earlier appearance of the reaction; in the other cases, on the other hand, in which alkalinity was not produced, its passage out of the stomach was delayed. Hydrochloric acid not only did not favor decomposition of the salol, but by increasing the tension of the pylorus it delayed the passage of the salol into the small intestine. Other irregularities in the time of appearance of the reaction were traceable to the varying influence of the nervous system on the motor function of the stomach.—*Medical Press*, July 18, 1888.

Albuminuria in the Insane.—According to the observation of KÖPPEN, of Strassburg (Verslg. d. Südw.-deutsch. Neurologen u. Psychiater), albuminuria is frequent in those with mental disease and sometimes has important and intimate relations thereto. Albuminuria has been observed: 1. In mental disturbances following upon chronic nephritis; an increase of albumin in the urine is concomitant with a condition of stupor and prostration, while a diminution is attended with clearness of mind. 2. In psychoses having their origin in arterial sclerosis. 3. In various forms of delirium, in which the stupor and mental disturbances increase in the same degree as the albumin in the urine. The albumin appears in its ordinary form or as propeptone. Köppen concludes that the albuminuria is caused by certain, yet unknown cerebral influences.—*Wiener medizin. Presse*, July 1, 1888.

Mercurialization in Lying-in Women.—DR. ROBERT BOXALL, at a late meeting of the Obstetrical Society of London (*Lancet*, July 14, 1888), read a paper on the "Conditions which Favor Mercurialism in Lying-in Women, with Suggestions for its Prevention." The question was debated under two separate headings—(1) increased absorption, (2) defective elimination. Under the first head, the site of absorption was discussed; the question whether the solution obtains entrance to the cavity of the uterus when the uterine tube has not been employed was debated, and an experimental investigation undertaken, with a view to determine the point, was related. It was suggested that absorption not infrequently occurs inside the uterus, even when the uterine tube has not been employed, but that it may also take place through the lacerated surfaces of the cervix, vagina and perineum or even through the intact mucous membrane. Reference was made to the experimental research conducted by MM. Doléris and L. Butte, which bears on this point.

With a view to diminish the risk of absorption, it was suggested (1) that not only should care be exercised to obtain contraction of the uterus, but that it should be also carefully maintained, and, above all, that the douche should always be given at such a temperature as will stimulate the uterus to action; (2) that the douche should invariably be administered in the supine position, the uterus at the same time being supervised by one hand placed on the abdomen; (3) that, when the administration is completed, the precaution should invariably be taken of ascertaining that the uterus is contracted by palpating the abdomen, and, if distended, the fundus should be squeezed like a sponge in the palm of the hand and at the same time should be depressed, with the object of evacuating the vagina; and (4) that the surfaces of lacerations about the external orifice should be brought together, and any abrasions which remain should be coated with some material impervious to the solution. Under the second head, the relative eliminative power of the different excretory organs was discussed and especial attention directed to the condition of the kidneys and intestine. The following suggestions were offered: (1) That chronic nephritis, and probably also those changes which occur in the kidneys during pregnancy, may, by diminished elimination, produce an accumulation in the septum; and (2) that the intestine possesses an equal if not a greater eliminating power than the kidneys. With a view to obviate the risks arising from defective elimination: (1) That when the kidneys are affected the sublimate douche should not be employed, or, if used, extreme caution should be exercised; (2) that a free watery flow should be promoted by the kidneys, and that especial care should be directed to this point in hot weather; and (3) that the bowels should be evacuated daily, either by salines or by the administration of such agents as produce copious and loose stools. A tabulated series of eleven cases which presented symptoms of slight mercurialism was appended, and also a fatal case of mercurialism narrated.

The Mechanical Treatment of Erysipelas.—Instigated by the results which Barwell, Freer and Otto obtained by painting with white lead the skin at the borders of erysipelatous inflammations, WÖLFLER (*Mitth. d. Ver. d. Aertze Steiermarks*) undertook some experiments with the mechanical treatment of erysipelas. Concluding that merely painting the skin with varnish—to prevent the admission of air necessary to the life of the coccus of erysipelas—did not suffice to limit the extension of the inflammation, he attempted the simultaneous application of a compressing band, by means of water-tight material and a bandage, and by means of gutta-percha paper prepared with chloroform (traumaticin), but with varying results. Guided by the idea that the application of the bandages was operative less by exclusion of air than by mere mechanical compression, he concluded to replace the bandages and strips of traumaticin by simple strips of adhesive plaster about an inch wide. In four cases thus treated, the author obtained good results; in no case did the inflammation extend beyond the strips of plaster; while in twenty-four cases treated with traumaticin, extension took place in five. The strips must be applied to the healthy skin at the borders of the inflamed area. In severe cases of erysipelas of the head, the hair must be removed; in advanced facial erysipelas, the strips should be applied about the neck. The author ascribes the results of the method, which commends itself for its simplicity and convenience, to the compression, which interposes a greater obstacle to the spread and development of the coccus of erysipelas than the ordinary antiseptic or antacid methods hitherto in vogue.—*Wiener medizin. Pr.*, July 1, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 18, 1888.

THE CONTAGION OF PNEUMONIA.

Now that the treatment of pneumonia is receiving an unusual amount of consideration, it may be well to revert, briefly, to some of the other aspects of that disease; and perhaps it is just the fashion of speaking of it as "that disease" that has led to a great deal of aimless discussion concerning its treatment. It was a fancy of Wunderlich's to say that if we could see the lungs as we see the skin, we would have as many varieties of pneumonia as we have of eczema, and perhaps, if we followed up the thought, if we said "those diseases," rather than "that disease," the debating ground would become much plainer. Certainly the researches of the last few years into the causes of pneumonia have not tended to prove the unity of its causation, while all the weight of evidence goes to prove that a variety of microorganisms, of widely different orders, may produce pneumonias histologically similar. For this reason our knowledge of the etiology of pneumonia is far less than that of many diseases apparently more recondite, though it is even now possible to make some leading generalizations of interest and even to draw some conclusions of practical importance. This has just been done by NETTER, in a very thorough and comprehensive study (*Arch. gén. de Méd.*, Juillet, 1888), and, while his results do not depart essentially from what was known or generally believed, they are interesting from the application he gives them.

According to Netter, pneumonia is a transmissible, contagious disease. The contagion is due to specific, pathogenic microörganisms, which multiply in the diseased focus, and which, leaving the body in various ways, are especially abundant in the products of expectoration. Contagion from the sick is still possible, long after recovery, and for two reasons. The first is: the contagion resists desiccation and may thus preserve its activity outside of the body, on indifferent substances, to which it adheres. The second reason is that the contagion is not destroyed in the patient after the termination of the disease, as are most infectious germs. Long after recovery, perhaps indefinitely, the subjects of the disease have in their mouths active germs, and this activity explains the great number of recurrences in pneumonia and the occurrence of multiple outbreaks in one family or house. The importance of these views, if correct, must be very great, and their bearing on prophylaxis must be of prime importance.

In regard to isolation, great advances have been made in late years over the views formerly entertained. Netter does not believe that a rigorous isolation is necessary in pneumonia. The relatives should not be allowed to pass the night in the same room with the sick, much less occupy the same bed. The danger of the well using the handkerchief of the sick, or *vice versâ*, is not entirely imaginary. In hospitals, cases of pneumonia should not be in small wards, or, if so, should at least be alone. The contagion is but feebly diffusible, and all the cases published show that contagion is especially liable to occur in small rooms badly aired. It is particularly necessary to avoid exposing patients with typhoid fever, acute exanthemata, acute affections of the respiratory tract, nephritis and diabetes to the danger of pneumonia. The tuberculizing influence of hospitalism, in these conditions, is well recognized, and it is quite as true that the diseases named favor the development of pneumonia.

The sputa, being the habitual if not the only vehicle of contagion, must be disinfected. So far as our present knowledge goes, corrosive sublimate is the best means we have for this purpose. In hospitals having disinfecting apparatus, the clothing and linen of cases of pneumonia should be submitted to the same process as in other contagious diseases. Other indications might be drawn from the modern idea of the persistent activity of germs in the mouths of recovered persons, though this is evidently a subject too new for profitable discussion.

These views we believe to express all that can at this time be safely concluded from the study of the microbic origin of pneumonia. Before we can dogmatize about treatment, it would be well to wait, not only until our knowledge of causes is greater, but even until we have made a more careful clinical study of the natural history of the disease than has yet been done.

THE COLLECTING OF STATISTICS, AND THEIR VALUE.

Hunting, when the object sought for is difficult to find, grows in interest, especially in matters of science, with the scarcity of the object to be discovered; and each new success adds to the satisfaction of the investigator. Tastes in science differ to such a degree that what may be the delight of one man may be an incomprehensible passion to another. If the heart be not in the work, the labor is simply drudgery, and the satisfaction lies only in getting through with it.

It is easy to comprehend the interest that is taken in the discovery of the remains of an extinct animal and its restoration to form, so as to show its size and peculiar characteristics, for many who have little taste for natural science, experience a certain degree of pleasure in looking at the mounted skeleton; but it is not so readily understood how a man can take pleasure in a lifelong study of the family of bivalve shells, or of butterflies and moths, or of the less attractive beetle and spend his days in collecting thousands of specimens. Many of the *lepidoptera*, it is true, are beautiful in the delicate colors of their plumage, for the butterfly has feathers as well as the gorgeously tinted humming-bird; but where are the attractions of beauty in the *coleoptera*, except in the few blue, green and golden beetles? An astronomer of this city, long since dead, developed in youth a passion for mathematics and later in life a love for the study of the starry heavens, and chemistry; but he could never comprehend how any one could find an interest in entomology and, in fact, felt almost a contempt for what he denominated a "bug-man." One man regards as dry and uninteresting a branch of study that is the delight of another. We are born with certain tastes, which are developed by opportunity, and the more decided is the innate passion, the more pleasure is there in its cultivation.

Collecting surgical statistics is a dull, tiresome work to one whose aim is to find the cases contained in books and journals and then consider his labor completed; but to another, whose real work begins where that of the former ends, the labor is one of satisfaction, if not of decided pleasure. In the cause of science and humanity he disregards all difficulties, and as these may increase before him, they only stimulate him to make his record thorough and complete. *Perseverantia vincit omnia* is his motto, as it was with the celebrated anatomist, Hyrtl, who, convinced in his own mind that it was possible to prepare a certain form of injected work, persevered with specimen after specimen until, upon the fortieth trial, he achieved success.

A tabular record should represent not only the cases that have been published, but, also, all that can possibly be collected by correspondence. It should always be arranged chronologically. If an operation is to improve in the percentage of its successful issues, it is important that the cases reported should be presented in the order of their occurrence and that the causes of increased success should be specially noted in the explanatory text. There is very little value in a statistical table that simply states how many patients survived and how many died. It is desirable to know why one lived and another died; whether death was due to a prior condition of disease or directly to the operation; what were the pulse, temperature and general health of the patient immediately before the knife was used; what increase of danger was due to delay in operating; what special method of operating was followed in each particular case; and which form of operation was attended with the least measure of fatality.

The best records are usually those which are confined to the country of the investigator; but not always so, for petty jealousy may sometimes refuse to a neighbor what will be granted to a distant correspondent—we might give several proofs of this fact that have occurred under our own observation. Working by correspondence is most effective and agreeable when two or more, each in a different country, are making investigations and exchanging notes. Thus the first comprehensive Porro record was prepared in Philadelphia and Vienna, and the second in America, England and Italy. As many as five nationalities have been represented in one record, and at present the Sänger Cæsarean method is being investigated by an American, a German and an Italian, all working to the same end and simply with a view to reduce the mortality of an operation long regarded as one of the most fatal in surgery, by disseminating a knowledge of what has already been

accomplished in careful hands. Making searches in a foreign land can readily be carried out, and unpublished cases may often be more easily obtained than in our own country. Few men know how to record accurately their own operations, and some important points will often be left out, even by the best. These must be ascertained by letters of inquiry, in the sending of which there need be no hesitancy, as replies are usually given promptly and courteously.

It is rarely safe to accept, as correct, the work of other statistical writers. The disposition to save trouble, by accepting the data of earlier investigators, has kept in existence errors of long standing, which are now so firmly established that it is almost impossible to get rid of them; such are some of the early fabulous cases in obstetrics and abdominal surgery, as well as others of more recent date. What may be termed student-made researches are apt to contain numerous errors, such as are exhibited to a marked degree in the tables of Dr. Fleetwood Churchill. Hurriedly made collections are generally imperfect. Years have been, in some instances, required for making a satisfactory private research, and, thereby, cases long hidden away have been brought to light for publication.

The following rules will fill all the reasonable requirements of statistical work:

1. A tabular record should be prepared before the general text is written, and the latter should be based upon the facts taught by the former.

2. It is safer to prepare this record *de novo*, than to make it a continuation of the work of a possibly inaccurate predecessor.

3. The cases should be arranged chronologically, and the tabular headings should represent the important facts of each case and operation.

4. Attention should be specially given to the unrecorded cases, which can only be obtained by correspondence, often perseveringly kept up.

5. The record of each case should tell, if possible, the reason for recovery or death; and whether the result was due mainly to the prior condition of the patient, or to the operation.

An epidemic of yellow fever has developed at Jacksonville, Fla., within the past ten days. People are leaving the city by every known means of exit, but these avenues are being rapidly cut off, and the city already is practically shut in on all sides. Fumigating and inspecting stations are being established under the direction of Surgeon-General Hamilton at all points necessary to make complete the cordon intended to protect Georgia and the surrounding States, which have declared a rigid quarantine against Florida. All infected bedding and clothing is ordered to be burned. The city itself is being depleted, and a camp of refuge for the well, in charge of Dr. Guitéras, of the U. S. Marine Hospital Service, has been established at Bourgoyne, thirty-six miles west of Jacksonville, on the Savannah, Florida and Western Railroad, the National Government supplying the tents. The sick will not be allowed to remain there, but will be sent back to Jacksonville for treatment.

The committee of the German Chirurgical and Berlin Medical Societies for the establishment of a Langenbeck memorial, has issued an appeal for contributions. The memorial is to consist of a building for the purposes of medical societies and the collection of scientific works. The late Emperor was at the front of the movement, as well as the Empress Augusta.

The Barcelona Academy of Medicine and Surgery has offered the Gari Prize of 1500 marks ($375) for the best essay upon The Pathogenesis of Gonorrhœa (its Clinical Varieties, Complications, Prophylaxis, with Drawings). The paper must be written in Spanish, French or Italian, accompanied with the usual motto, and handed in before June 30, 1889.

The distinguished anatomist, Prof. Wenzel Gruber, on account of his health, has given up his work in Russia, and left St. Petersburg, to take up his residence in a milder climate. Setchenow, Professor of Physiology at the University of St. Petersburg, upon the completion of thirty years of teaching, will also shortly withdraw from the University.

The Pennsylvania and Maryland Medical Union meets this year at Birmingham Park, Chester County, Pennsylvania, on August 30th. Addresses will be delivered by the President, Dr. Rouse, of York, and others.

The Mississippi Valley Medical Association meets at St. Louis, September 11th, 12th and 13th next. The Society extends a cordial invitation to all members of the profession to attend its meeting. Arrangements for special rates are being made. The first day will be given to the discussion of abdominal surgery; the second, to infant feeding and some obstetric subject. The third day will be taken up with

volunteer papers and a discussion on some neurological subject.

The authorities of the University of Montpellier have determined to celebrate the sixth centenary of the foundation of the University, at the commencement of the scholastic year, 1889–1890, and foreign universities will be invited to send delegates.

A list of Chinese medicines, printed for the use of the customs officers of the Treasury Department, reminds us of the strange pharmacy of the mediæval period in Europe. They are imported chiefly for the use of the Chinese doctors of the Pacific slope, and include such alleged substances as tigers' bones, rhinosceros' horn, elephants' gall, asses' glue, snake-skins, fowls' gizzards, dried silkworms, crabs' eyes, dragons' teeth, hedge-hogs' skins, fossil crabs, fossil teeth, horse-tails, straw, glass, cow-hair, Job's tears, "insects of nine smells," puff-balls, ground blood, cows' knees, tree-bugs and centipedes.

At a recent session of the County Court, at Pittsburg, an interesting case was decided in regard to the amount of a bequest to the Hospital for the Ruptured and Crippled at New York City, the gift being that conveyed by the will of Mrs. Alice B. Schoonmaker. The question at issue was to determine whether the amount of the donation was two thousand or ten thousand dollars. The decree of the court awarded the larger sum to the hospital.

There are 16,930 practising physicians in England, a proportion of 1 to every 1642 inhabitants; and an increase in number of 21.7 per cent. since 1881. The largest number is found at Brighton, where there is 1 physician to 727 persons; next comes London with 1 to 939.

Prof. Salvatore Tommasi died at Naples, in his seventy-fifth year. He was equally distinguished as a physician and teacher. Tommasi was born in 1813 and graduated in medicine in 1838. He was made professor of internal pathology in 1844, which position he lost in 1849 through political causes. After a sojourn on the Continent, he studied physiology and clinical medicine at Turin. Here he completed his principal work, *Manuale de fisiologia*, which ran through three editions. In 1865 he became professor of the medical clinic at Naples, after having occupied the same chair at Pavia for five years.

Prof. Krafft-Ebing, of Gratz, will succeed Prof. Leidesdorf in the conduct of the Insane Clinic at Vienna.

REVIEWS.

Cholera and Water in India. By M. C. Furnell, M.D., F.R.C.S., Companion of the Indian Empire, Fellow of Madras University, late Surgeon-General and Sanitary Commissioner, Madras, etc. 8vo. pp. 45. London: J. & A. Churchill, 1887.

This is a popular lecture delivered at Madras in 1882, in which the author cites facts in support of the statement that water is the chief means by which cholera is spread, especially in India, and that on account of the *peculiar treatment* of water in India that country is constantly subject to the most terrible epidemics of this scourge. The experience of towns which have abandoned polluted water is presented as proof of the proposition that a pure and uncontaminated water supply is the thing most essential in conferring immunity from this disease. The lecture closes with practical suggestions on the water-supply of India.

The Physicians' Leisure Library. Number 7. The Modern Treatment of Pleurisy and Pneumonia. By G. A. Garland, M.D. George S. Davis, Publisher.

Although we are more than ever convinced of the difficulties and dangers involved in making books on treatment, to the exclusion of pathology and diagnosis, we must admit that in the present instance the author has so combined a judicious selection of the material and an attractive style as to furnish a very readable volume. Nor has the author omitted all mention of diagnosis. Under the heading "thoracentesis" there is a description of some of the diagnostic features of pleural effusion. Pathology is so far represented that as much space is devoted to the etiology of pneumonia as to its treatment, though it must not be supposed that the treatment recommended is based on the advances in pathology here considered. We rather wish the author had illuminated that other dark chapter in medicine, the etiology of pleurisy. Those who wish a clear and concise guide to the treatment of pleurisy and its complications, and a short account of the various forms of treatment of pneumonia, not all of them "modern," will find what they wish in this volume. The proof-reading would bear improvement, the names of foreign journals being incorrect wherever there is the possibility of error.

Proceedings of the New York Pathological Society for the Yeay 1887. By John C. Peters, M.D., Editor. Printed for the Society.

The most important part of these proceedings is that taken up by the Middleton-Goldsmith lectures of Dr. M. Allen Starr, on "Multiple Neuritis and its Relation to Certain Peripheral Neuroses." Beside this there is the usual abundance of reports and papers on anatomical specimens and other subjects of pathological interest. From the scope and object of the periodical medical press it seems of doubtful economy to compile a volume of proceedings from journal reports alone.

SOCIETY PROCEEDINGS.

CONGRESS ON TUBERCULOSIS OF MAN AND ANIMALS.

Held in Paris, July 25 to 31, 1888.

WEDNESDAY, JULY 25TH.

(*Specially reported for* THE MEDICAL NEWS.)

The Congress on Tuberculosis was opened in the hall of the Faculty of Medicine of Paris.

Prof. Chauveau, President of the Organizing Committee, was elected president of the Congress, with Profs. Villemin and Verneuil as vice-presidents.

PRESIDENT CHAUVEAU delivered the opening address, in which he gave an historical sketch of the recent progress which has been made in the study of tuberculosis, and which has resulted in its being considered as an infectious disease. The infectious nature of tuberculosis, which had been suspected by Morgagni, Andral and Laennec, is to-day, since the researches of Villemin, Koch, etc., a recognized fact. To-day the relation between human tuberculosis and bovine tuberculosis is also a recognized fact, and the possibility of the transmission of tuberculosis from animals to men is of no slight importance.

PROF. CORNIL, of Paris, presented a paper on

TUBERCULOSIS OF MUCOUS MEMBRANES.

One of the most important points to-day, he said, is the penetration of the tubercular bacilli by their simple contact with the mucous membrane. For the penetration of bacilli through the mucous membrane it is not necessary that the membrane be the seat of fissures, lesions or excoriations. All that is necessary is that the virus should be in contact with the mucous membrane. This results from the experiments of Chauveau, Villemin, Parrot, etc. These last experimenters have produced tubercular intestinal lesions in animals only by the ingestion of milk containing bacilli, or even cultures of these bacilli. MM. Tappeiner and Schottelius have also determined, by inhalation from liquids containing tubercular matter, tubercular lesions of the lung.

M. Dobroklousky, who has followed these experiments, has found that fifteen days after the ingestion of bacilli we find tubercles visible to the naked eye, and no trace of diarrhœa in those animals. The superficial epithelium was perfect. Peyer's patches are swollen, and between the cul-de-sac of Lieberkühn's glands we find accumulations of lymphatic cells. The lymphatic ganglia of the mesentery are the first to show tubercular lesions. On the fourth day accumulation of cells could be seen, and well-defined tubercles on the sixth day.

This year Prof. Cornil has studied several tubercular uteri; two of them belonged to old women. In these cases the sexual contagion is quite problematic; in one of them the tubercular lesion was localized in the neck alone, and the histological examination has shown some very characteristic tubercular granulations. The result of this examination, and the seat of the granulations beneath the epithelium in a woman having no pulmonary or peritoneal manifestations, made one believe in a tuberculosis due to sexual contagion. We have no proof of this, but this fact leads us to consider whether, as these tubercles were superficial, they were not due to the penetration of the bacilli from the surface. To establish this fact, Cornil introduced into the vagina of female rabbits, by a glass rod with a rounded extremity, so as not to wound the vagina, two or three drops of tubercular bacilli culture. These different animals were sacrificed, some six, twelve, twenty-four and thirty-two days after the operation, for the purpose of examination. For the first few days the lesions of the neck are those of a catarrh of the neck, great quantity of lymphatic cells, free in the cervical cavity or situated in the glands; a few bacilli are found amongst these cells. On the fifteenth day we see already the formation of small microscopical tubercular follicles beneath the normal epithelium; these small tubercles are immediately beneath the epithelial cells at the free extremity of the villosities or on a level with the glandular culs-de-sac or depressions of the arbor-vitæ. Thirty-two days after inoculation the tubercles can easily be seen with the microscope. This shows that a very small quantity of virus, introduced without any traumatic lesions, will produce tubercular lesions similar to those he had observed in the women. He believes that tubercular infection of the uterus is possible by the genital passage by a very small quantity of tubercular sperm.

We must observe that the epithelium of the neck is formed by a very superficial layer of cells, and that, like the intestinal mucous membrane, these cylindrical cells are easily penetrated, and do not hinder the penetration of liquids and foreign bodies like the stratified pavement epithelium. In this respect, of all the genital mucous membranes of men and women, that of the uterus is the one that opposes the least resistance. The pavement epithelium of the urethra, vagina and bladder is not altogether protective against the bacilli, for we have seen tubercle bacilli penetrate, with lymphatic cells, the mucous membrane of the pharynx; but this membrane was full of tubercles and also inflamed: the epithelial cells were separated "on account of the passage of these migratory cells, and this was the open path for the bacilli."

PROF. NOCARD, of Alfort, then read a paper on

THE DANGERS OF THE MEAT AND MILK DERIVED FROM TUBERCULOUS ANIMALS.

This question seems only to have occupied the mind of hygienists since the publication of the works of Chauveau, Gerlach, Klebs, Bollinger, etc., who have all shown that the meat and milk of tuberculous cows could be virulent; also since Toussaint demonstrated that in a tuberculous cow the blood, urine, tears and vaccine are as virulent as the caseous matter of tubercles.

The milk is only virulent when the tubercular lesions have invaded the glandular tissue; but it is a very difficult matter to recognize tuberculosis of the mammary gland in a cow and at the beginning of the disease, as it also is for a veterinary surgeon to affirm that a gland is not infiltrated with tubercular granulations; one must deal with the tuberculous cow as if the mammary gland was always tubercular. This is the result at which the committee on epizootics had arrived, and the sale of milk from tuberculous cows was forbidden, and only allowed to be given to animals after it had been boiled. In large cities we must never give raw milk, and must always tell the mother to boil the cow's milk before it be given to children. If sometimes it appears necessary to use raw

milk, he recommended the use of goat's milk, for he had never heard of this animal having contracted tuberculosis.

According to the works of Toussaint, it appeared that tuberculosis was a disease in which every part of the diseased organism contained in it the germ of the affection. Bouley admitted this view as well as the International Veterinary Congress of 1883; hence there was no hesitation possible, and every tubercular animal being a public danger was to be destroyed. In 1885, however, Arloing obtained his opinion from the Congress that the meat of a tuberculous animal should be discarded only when tuberculosis had become generalized and had extended beyond the glands in communication with the diseased part.

The Council on Epizootics has obtained an order from the State Council that tuberculosis should be considered as an infectious disease and assimilated to carbuncle. Every diseased animal is to be placed under the care of a veterinarian, isolated and sequestered; the meat to be excluded, if the disease has become a general tuberculosis. The skin can be utilized if disinfected beforehand, and the milk can be given to animals, but must be previously boiled. These measures are quite sufficient, for the meat juice of tubercular cows is rarely capable of communicating the disease.

Out of forty guinea-pigs inoculated with one cubic centimetre of meat juice derived from twenty-one tuberculous cows, one only had died fifty-nine days after inoculation. These facts, compared to those obtained by Galtier, H. Martin, Vallin, Arloing, Chauveau, etc., establish the fact, that tuberculosis can become generalized, if a tubercle ulcerates and opens into a vessel, setting free the bacilli it contains.

From a series of experiments, he found that the meat juice of inoculated animals ceases to be virulent about six days after inoculation; the only bacilli that will multiply are those that are thrown in a part where the circulation is favorable to their multiplication (liver, lungs, glands) the others which are caught in the muscles are rapidly destroyed. His experiments are certainly not perfect, for in his inoculation, he poured into the system all the bacilli at once, while, if a tubercular ulcer opens into a vessel, these bacilli are gradually and continuously poured out; and the danger of generalization by the muscular tissue certainly continues much longer than by his experiments; still it is not to be exaggerated, for he has fed twelve little kittens on tubercular meat for many days, without one becoming tuberculous, and we all know the susceptibility of cats to intestinal tuberculosis. This experiment is especially interesting, because amongst the cows whose meat has been given to these kittens was the one whose meat juice, introduced into the peritoneum of the guinea-pig, had rendered it tuberculous, and the kittens had eaten more than one pound of this meat without showing any signs of the disease. He concludes that the meat of tuberculous animals can be dangerous under certain conditions, but is very rarely so. Whenever it is dangerous, it is so to a slight degree.

JULY 26TH—MORNING SESSION.

DANGERS PRESENTED BY THE USE OF MEAT AND MILK DERIVED FROM TUBERCULOUS ANIMALS, AND HOW TO PREVENT THEM.

M. ARLOING, of Lyons, thinks that we can arrive at the suppression of tuberculosis amongst animals by strict sanitary measures, if tuberculosis be inscribed as a contagious disease, and if, on the other hand, the use of tuberculous animals' meat be prohibited until we find a method to render it innocuous.

He differs from M. Nocard, who, on inoculating forty guinea-pigs with meat juice, had obtained only one diseased animal. He, on the contrary, in his experiments with Prof. Chauveau, had obtained one success on two animals, and Galtier five out of twenty-two. He admits that out of twenty tubercular cows, four are capable of transmitting the disease through the meat. M. Nocard maintains that the muscular tissue is capable of digesting the tubercle bacilli; it is, indeed, a general law, that the microbes rapidly disappear in the blood and muscles, but this is not reassuring, since the animal possesses a tubercular lesion which is capable of supplying bacilli to the muscles all the time, and we cannot affirm that meat at the moment of the death of the animal does not contain microbes.

The large animals are more dangerous, because they are not suspected. As to the cooking of the meat, it is not always reliable, for M. Chauveau and himself have heated to 158° F., for half an hour, tubercle bacilli neutralizing but not destroying them, and we know that underdone meat has not been heated beyond 122° or 140° F. For his part, he objects absolutely to the use of tuberculous animals before we have found a way to neutralize this meat; M. Galtier has tried salting without very satisfactory results. The sanitary measures must not only be taken in the cities but also in the country.

M. BANG, of Copenhagen, said that he had studied, since 1884, to what degree cow's milk is virulent when obtained from tuberculous cows, with a healthy mammary gland. Out of twenty cows two only presented virulent milk; in eight phthisical women never has the milk been found so. The danger is much greater when the milk comes from a tubercular mammary gland; and he did not think, like M. Nocard, that this affection is so difficult of diagnosis. It begins by a diffuse tumefaction of a part of the mammary gland, secreting first a normal milk, which later presents a yellow serum; the secreted liquid is rarely purulent. This affection is not very rare, as we meet with cases every year. Koch's bacilli he has found in the different preparations of milk.

As to the influence of heat on the tuberculous milk he finds, that if milk is heated to 122° to 140° F. only, no benefit is obtained; a higher temperature will destroy its virulence much more. In two series of experiments, tuberculous milk heated to 176° F. produced tuberculosis by inoculation in one case but not in two others. Heated to 185° F., milk was always rendered innocuous. To six rabbits he gave raw tubercular milk; all became tuberculous, four of them remarkably so; two other rabbits took the milk heated to 140° F., two took it at 149° F.; of these four, two only, one of each section, took the disease. Six rabbits who took it heated to 158° F., and two at 167° F., showed no sign of the disease.

M. BAILLET, of Bordeaux, said that his conclusions are far from being in accordance with those of M. Arloing, and rather resemble M. Nocard's. He certainly believes in the transmission of tuberculosis from animals to man, but he does not think it necessary to destroy the meat derived from any tubercular animal. At Bordeaux, out of 22,000 cattle only 40 were found tuberculous, and

out of these 40 only 15 had general accidents; while if we examine the official statistics we find that out of 250,000 inhabitants, 1000 are phthisical, hence the propagation from animal to man must play a very unimportant part.

His conclusions are: As there is no complete identity between the results obtained by accidental or experimental inoculation of tubercular products and those resulting from the direct ingestion of meat derived from subjects suffering from tuberculosis; that the penetration of the tuberculous virus through the digestive tract is an accidental fact, far from being demonstrated; and that it is not sufficiently demonstrated that the meat of fat animals, which have a few tubercular lesions or believed such, are capable of transmitting tuberculosis to man; and as it would be a great loss in a commercial point of view to suppress all these fat animals, he believes that, 1st. Meat obtained from tubercular subjects in whom tuberculosis has become generalized, ought to be discarded; 2d, that, as regards fat animals, during the life of which the existence of tuberculosis was not suspected, the suppression of the meat must take place only if the lungs, pleuræ and lymphatic glands show tubercular lesions; and, 3d, that, in the other cases, it is quite sufficient to suppress from use the organs only which are more or less affected by the disease, and the afferent lymphatic glands and neighboring muscular parts.

M. Butel, of Meaux, thinks that we have no right to look to the commercial view of the subject, but rather to the sanitary view; no half measures must be taken, for the danger is great; he cannot himself see why a difference should be made between animals affected by a local tuberculosis and those presenting a generalized affection. We cannot affirm that the meat is in a healthy condition. If we only use half measures; we observe that in Paris only 11 cattle are taken out 263,000. He held that the meat of phthisical animals ought always to be destroyed, and as to the milk, that boiling it is the safest preventive from infection through its medium.

M. Grissonnanche, of Aiqueperse, said that as bovine pulmonary phthisis is observed especially amongst cattle living in herds, it would be important to separate the animals that cough from the others; this would diminish the chances of contagion. The bovine cattle in his district live from four to five months in the open air, without being protected from rain. In the fall they are brought down from the mountains and placed in low hovels, well closed, where air can hardly penetrate; men even will live with them in those places, which are most favorable to contagion. Bovine tuberculosis being transmissible to different species of animals, one can say without hesitation, that it is as easily transmitted to man.

M. Veyssière, of Rouen, said that veterinary surgeons must possess a well-defined sanitary regulation, one there can be no two ways of interpreting. In case the Congress should not adopt radical measures in regard to tuberculous meats, it ought to specify accurately what lesions will forbid or allow the use of these diseased meats. Intestinal tuberculosis is not so very rare, as is generally supposed, and the influence of food is not to be disregarded in studying the etiology. He gave the following on this point. In Rouen, out of fifteen cases of intestinal tuberculosis in pigs, three of them came from a knacker and six from milkmen in the neighborhood of Rouen. On the other hand, he has observed in four years, four cases of tuberculosis of calves; two presented a general tuberculosis, two exclusively intestinal lesions. Is that not a proof that tuberculosis is often due to the food used? As to the appearance of the animals, we have to be careful; having seized a very fat cow, and having injected meat juice obtained from her, to two rabbits, they both died.

M. Spillmann, of Nancy, said that tuberculosis is very frequent on the Eastern frontier, and takes the contagious form; the cows are in bad hygienic condition, and they are carelessly exposed to contagion, for when one of them dies of the disease no precautions are taken. The mortality of cows from phthisis is thirty to forty per cent.; they are bought at a very low price and sent to the neighboring market, with all the danger of infection. The surest method to prevent such facts from occurring would be to require a certificate of origin, and to recommend the destruction of any diseased animal, presenting even localized tuberculosis.

M. Rossignol, of Melun, thought that the measures proposed by M. Nicard are amply sufficient, but these measures are never carefully applied on account of the resistance of the proprietor or the weakness of the veterinarian. To render them applicable, proprietors of diseased animals ought to receive a compensating indemnity; and the Congress ought to insist and demand of the Government, the consideration of this subject. As regards the milk, it is more difficult, for we cannot prevent a cattle-breeder from doing with it what he likes.

M. Guiraud, of Montauban, said that in his city, for the past six years, 63 phthisical cattle were found out of 15,473, or 4.7 per cent. About 4 animals out of 1000 are seized, but this proportion is not very correct, for the cattle-breeders kill these animals outside the limits of the city, and introduce their meat in pieces. He thought that all tuberculous meat ought to be suppressed; this winter he had seen a fat ox, which obtained a medal, and presented well-marked tubercles.

M. Moule, of Paris, had observed the frequency of tuberculosis in fowls; this tuberculosis seems to localize itself more particularly in the abdominal viscera, and particularly the liver; hence the danger of infection through this organ, which is often used in the preparations of certain dishes. For a fowl to be sold it ought to be alive, in good health; and if dead, ought to be quite fat, otherwise the viscera ought to be kept in the abdominal and thoracic cavities for examination.

M. Villain, of Paris, stated the method of procedure at the slaughter-houses of Paris; if tuberculosis is localized, and if the animal is fat, the meat is allowed for sale; when the diseased part is suppressed, the animal is entirely seized if there is a general tuberculosis; in a general way, the proportion of phthisical animals is 6 to 1000 in Paris.

Evening Session.

M. Siegen, of Luxembourg, had seen a great many tubercular animals at the slaughter-houses of Luxembourg, but has always found it impossible or difficult to distinguish between the two grades of local and general tuberculosis, and he preferred radical measures. He has also succeeded in producing tuberculosis in four pigs which were fed on meat coming from a tuberculous cow. The only way, according to him, to suppress the diseased meat, is to cremate the infected animals.

Dr. Robinson, of Greenock, did not believe in the half-way method of destroying only the animals present-

ing general tuberculosis; for the past fourteen years, during which he has been meat inspector in Scotland, he found that cases of tuberculosis in animals are rare; and where tuberculosis appeared, on first examination, to be perfectly limited, he found tuberculous lymphatic glands. He came to the Congress for the sole purpose of asking the most radical measures, namely, that, as he thinks it impossible to choose between tuberculous animals, they must all be excluded, even if indemnities had to be given to the proprietors by the government.

M. LAHO, of Brussels, also insisted on excluding all diseased animals, supporting his opinion by the fact that amongst all the cows which have been slaughtered in Brussels, more than 4 per cent. were tuberculous.

The discussion on the first question was then closed, and the President presented the following

PROPOSITION.

"It is necessary to pursue by all means, including an indemnity to the proprietors, the general application of the seizing and total destruction of all the meats obtained from tuberculous animals, whatever may be the specific lesions found in these animals."

This proposition was carried by the great majority of the members of the Congress. Three members only opposed it: MM. Nocard, of Paris; Laurent, of Bar le Duc; Corrado Massa, of Genoa.

HEPATIC AND PERIHEPATIC TUBERCULOSIS.

M. LANNELONGUE, of Paris, said that a few years ago, in a communication to the Academie des Sciences, he called attention to the perihepatic tubercular abscesses, an abscess but little known from a clinical point of view, and the nature and origin of which remained in the dark. He then thought that the liver surface would be one of the origins of these abscesses; since that time he has demonstrated three cases showing intrahepatic tuberculosis, which gives the explanation of certain perihepatic abscesses. The following are the cases:

Case I.—Boy, of thirteen years, had a subhepatic abscess, which had been opened, scraped and inferior border of thorax excised; two months and a half later he died from pleurisy. At the post-mortem, the seat of the trouble was in the liver. At that place a section showed a caseous hepatitis of nearly the entire right lobe; near the anterior border was a soft spot presenting a cavern, the size of a large chestnut, containing caseous, flocculent pus.

Case II.—Girl, of four years, suffered from a subhepatic abscess. This abscess was opened, scraped and the inferior border of thorax resected. At the post-mortem, the right lobe of the liver, opposite the subhepatic abscess, was the seat of two tuberculous abscesses, one of which was divided in two by a partition; the three pockets were filled with caseous pus.

Case III.—Girl, of two years, subhepatic tubercular abscess, occupying the epigastrium and the region of the left lobe of the liver; general symptoms alarming. To destroy completely the subhepatic abscess he resected the lower border of the left thorax. This abscess being well scraped, the liver appeared perfectly healthy, but, by pressing on the organ, he found that pus came out by two orifices distant from each other by one inch, both leading to a single cavity, about the size of a small nut, located in the middle of the hepatic tissue. The two openings were united by the aid of the thermo-cautery; but the child died four days later from general tuberculosis.

If we consider these three cases from an anatomical point of view, we find the existence of two forms of hepatic tuberculosis (outside of tubercular granulation): tuberculosis by infiltration or caseous hepatitis, and cavernous ulceration or tubercular abscess of the liver.

In a clinical point of view, hepatic tuberculosis has no particular signs so long as it is limited to the liver; when combined to perihepatic abscess we can suspect it, for out of seven cases of abscesses three times has he found a tubercular hepatitis the origin and source of these abscesses.

The treatment of the intrahepatic abscesses will only be a secondary stage of the treatment for the cure of perihepatic abscesses, as the diagnosis is too uncertain to be made at once. In these cases of abscess we must examine the liver carefully and evacuate it if necessary, and resect the lower border of the thorax, without rejecting, however, in limited and benign cases the injections of iodoformed ether.

ON AN ORGANISM DIFFERENT FROM KOCH'S BACILLI FOUND IN THE TUBERCULAR LUNG IN MAN.

M. SOLLES, of Bordeaux, said that this organism can be demonstrated first, by inoculation of rabbits with tubercular matter obtained from the human lung. These animals which have been inoculated die after a time, varying from four months to a year, of a disease quite different from tuberculosis, presenting constant and characteristic lesions and a special microörganism. Culture of the rabbit's blood always gives the same organism. By inoculation of this same culture to guinea-pigs and rabbits it produces in these the same pathological influence.

It is demonstrated in phthisical persons by the presence of these same organisms in the sputa and blood of phthisical persons. In sputa the demonstration is a very easy one; in the blood it is more difficult on account of the coagulation of fibrin; but the culture of the same blood on different mediums renders its presence certain.

This organism, which has been taken up to the present time for an insignificant bacterium, is not the tubercle bacillus of Koch; for it does not respond to Ehrlich's reaction as Koch's bacillus, or the one of leprosy. This microörganism looks more like the microbe of erysipelas. In a word, the infection of which he spoke presented the character of a true septicæmia associated with tuberculosis.

STUDY OF TUBERCULOSIS IN LIMOGES.

M. BOULLAND, of Limoges, said that in his city tuberculosis is very unevenly distributed. The poor quarters in the neighborhood of the river and the district occupied by porcelain workmen, the bronchi of whom are continuously irritated by the dust of porcelain clay, are those in whom tuberculosis is more prevalent. In a certain quarter where prostitution is very free, it is also extensively prevalent, which he attributes to contagion through the genital passages. He thinks that not only ought the prostitutes who suffer from venereal disease to be eliminated from those quarters, but also those presenting signs of pulmonary tuberculosis.

TUBERCULAR MENINGITIS IN THE ADULT.

M. Kalindero, of Bucharest, said that he was convinced that tubercular meningitis of the adult is often difficult of recognition; that in children we might have certain slight attacks which disappear and leave no trace; that in the adult these irregular forms are capable of originating certain forms of insanity. Finally, that meningitis of adults can be localized in certain convolutions and become chronic.

ON TUBERCULAR MENINGITIS DURING PREGNANCY.

M. Chambrelent, of Bordeaux, has had the opportunity to observe three cases of tubercular meningitis in pregnant women, at different periods of gestation, and to make the post-mortem examinations. He concludes that pregnancy does not seem to have a very marked influence on the progress of this disease; that the disease, even at its extreme period, does not seem to influence in any way gestation, or the health of the fœtus. He considers that we are entitled to produce premature labor when the woman has passed six and a half months, and the diagnosis of tubercular meningitis has been well established.

TUBERCULAR HEREDITY AND PREGNANCY.

M. La Torre, of Messina, from his researches, concluded that if the father is in a perfect state of health, we constantly shall see the fœtus arrive at a normal development and at the usual time, whatever may be the state of health of the mother. If now the mother is in a perfect state of health and the father, on the contrary, is in a poor condition, the fœtus will never reach in weight above five pounds. Alcoholism, syphilis and tuberculosis can influence the development of the fœtus; and in regard to this last disease, as a result of his experiments on guinea-pigs, he finds that the tubercular spermatic fluid is capable of rendering the ovule tuberculous. Hence, a tubercular father can transmit to his offspring, not only a poor, predisposing condition to the disease, but also the specific disease itself, and a general tuberculosis of the father can very well interfere with the development of the fœtus.

TUBERCULOSIS AND VACCINATION.

M. Degive, of Brussels, drew attention to the proceeding followed in Belgium to obtain pure vaccine virus. When vaccine virus has been obtained from a calf, prepared for that purpose, the animal is killed and a post-mortem made. If it is healthy and shows no trace of tuberculosis, the meat is allowed to be sold; if on the contrary it is tubercular, the vaccine derived from it is immediately destroyed. In less than two months sixty thousand persons have been vaccinated in Belgium without the slighest danger of contamination.

President Chauveau did not think these precautions necessary, admitting that in Paris such precedures were not followed—the vaccine virus is rarely tuberculous, it is very exceptional for it to be so; moreover, experience has shown that it is very difficult to inoculate tuberculosis on a superficial erosion. In presence of these facts it was not necessary to be so strict about vaccination, for we frighten away a good many people from being vaccinated at the expense of the health of the community.

CORRESPONDENCE.

WARNING AGAINST CHLOROFORM INHALATION IN CHILDREN.

To the Editor of The Medical News,

Sir: For more than eleven years I have placed great confidence in the ability of the tissues of children to resist the depressing effects of chloroform administered as an anæsthetic. Three days ago I was called to see a large, strong girl, between three and four years old, who had fallen upon a large pin, breaking off about one inch of it, which was deeply imbedded along the inner side of the right brachial artery, an inch and a half above the elbow. As the child would not permit any attempt at removal, I administered chloroform, which she strongly resisted. Having removed the stopper from a two ounce phial of the drug, I placed a folded handkerchief against the mouth of the bottle and overturned it twice, which was repeated a second time before the anæsthetic took effect. Afterward, upon examining the phial, it was found that less than one drachm had been employed.

Without the slightest warning symptom, just as an incision was made, there was a sudden blanching of the entire surface and not a drop of blood flowed. To my ear the heart sounds, as well as respiration, had ceased, the child seemed to be dead. Immediately its body was inverted, artificial respiration began, and ammonia applied to its nostrils. In about five minutes, which seemed much longer, an attempt at inspiration was made. Copious emesis occurred in about fifteen minutes, and in an hour the heart beat was rapid, weak and regular.

Charles Baum, M.D.

630 N. Broad St., Philadelphia, Aug. 14, 1888.

A VALUABLE REMEDY FOR DIARRHŒA.

In answer to an inquiry as to the administration of the remedy recommended for chronic diarrhœa, in The News of August 4th, page 139, M. C. L. informs us that the proper quantity of the chocolate tannin powder to be used is a heaped tablespoonful, which is to be cooked with milk for half an hour, and taken at the morning and evening meals. The quantity named makes a breakfast-cupful.

NEWS ITEMS.

Congress of American Physicians and Surgeons to be held in Washington, September 18th, 19th, and 20th, 1888.

The American Orthopædic Association announces the following preliminary programme:

The Modern Treatment of Chronic Joint and Spinal Disease, by Newton M. Shaffer, M.D., of New York.

Immobilization in Articular Disease.—Reports on the Treatment of Club-Foot by means of the Thomas Wrench, or the "T. T.," by V. P. Gibney, M.D., of New York.

Mechanical Treatment of Senile Coxitis, by Henry L. Taylor, M.D., of New York.

A Practical Point in the Treatment of Pott's Disease of the Spine, by A. B. Judson, M.D., of New York.

An Efficient and Inexpensive Method for the Mechanical Treatment of Pott's Disease, by C. F. Stillman, M.D., of New York.

Rest, in the Treatment of Chronic Joint Diseases, by John Ridlon, M.D., of New York.

Acute Epiphysitis in Infants, by Dillon Brown, M.D., of New York.

Remarks on Lateral Curvature and its Early Treatment, by Samuel Ketch, M.D., of New York.

Osteotomy for Anterior Tibial Curves, by DeForrest Willard, M. D., of Philadelphia.

Description of an Apparatus for Measuring any Inequality in the Lengths of the Lower Extremity, by T. G. Morton, M.D., of Philadelphia.

Hæmatoma Oris, as a Sign of Injury to the Spine in the Superior Cervical Region, by Benj. Lee, M.D., of Philadelphia.

Two Knee-Joint Excisions, by A. J. Steele, M.D., of St. Louis, Mo.

Report on Morton's Operation for the Immediate Reduction of Club-Foot, by H. Hodgen, M.D., of St. Louis, Mo.

Femoral Osteotomy, by Ap Morgan Vance, M.D., of Louisville, Ky.

A Case of Reflex (?) Valgus, by George W. Ryan, M.D., of Cincinnati, Ohio.

Remarks on the Operative and Mechanical Treatment of some Joint Diseases and Injuries; with especial reference to the Hip, Knee and Elbow Joints, with illustrative cases, by W. R. Whitehead, M.D., of Denver, Colorado.

Analysis of Treatment of Seventy Cases of Club-Foot, by E. H. Bradford, M.D., of Boston, Mass.

Bacteria in Ice.—Bacteria, it is now generally known, are not destroyed by temperature as low as the freezing point. At a temperature of 32° to 39° F. bacteria become dormant and are incapable of propagation, but retain their vitality. Experiments have shown that bacteria exposed to a temperature far below zero have, upon being warmed to 43°–54° F., been enabled to resume all their normal functions. It is, therefore, certain that ice frozen naturally or made by artificial processes from ordinary water may contain bacteria and germs. Dr. Carl Fränkel, of the Hygienic Institute, in Berlin, has made some observations in this direction, which have been published in the *Zeitschrift für Hygiene*. Dr. Bischoff, of Berlin, has also made chemical and microscopical examinations of the various kinds of ice, natural as well as artificial, for sale in Berlin. Many of the samples of ice thus examined were found to be as impure and unfit for use as the most impure and unwholesome drinking water. It was remarked that, while the greatest care is observed in the selection of wholesome drinking water, it is most astonishing how little thought or care is bestowed upon the more dangerous impurities contained in ice. The German government finally ordered the discoverer of bacteria, Dr. Robert Koch, to make an official investigation. The method of procedure was that of allowing a centimetre (16 minims) of ice to melt and cultivating the resultant water in gelatin. It was then found that seven specimens of ice, from as many different sources, contained in that quantity of melted ice, from 140,000 germs, the smallest number, to 880,000 germs, the largest number. It was thus conclusively shown that freezing does not destroy bacteria. The most remarkable thing was the varying results, but this can be accounted for by the method of examination and the time thus allowed to elapse between the melting of the ice and the examination. Enough has been shown, however, to prove that American experiments have been fully corroborated by the best European authorities.—*American Analyst*, July, 1888.

The Pharmaceutics of Antipyrin.—Antipyrin, although a fairly stable chemical body, undergoes decomposition in contact with certain substances, occasionally with an undesirable result. One of the most noteworthy incompatibles is the spirit of nitrous ether. This mixture gives rise to a green color, and although the precise nature of the resulting compound is not known, a child suffering from a slight fever, to whom it was given, died shortly after with symptoms strongly pointing to poison. It is, therefore, highly desirable that this incompatibility should be made known as widely as possible.—*Medical Press*, July 28, 1888.

A Princely Physician.—Prince Louis Ferdinand, of Bavaria, has passed the final medical examination qualifying him to practice as a physician. He is the second member of his family who has joined the medical profession.

Erlenmeyer's Morphia Disease.—Dr. J. B. Mattison, of Brooklyn, is translating Erlenmeyer's *Morphia Disease and its Treatment*, the latest and largest work on the subject, which, with notes and comments by the translator, will be brought out during the coming autumn.

CORRIGENDUM.

Resorcin in Summer Complaint.—Dr. Brooker writes to the *Maryland Medical Journal* that the dose of resorcin used at the Thomas Wilson Sanitarium (see The Medical News of July 28, page 99) is one-half grain and not two grains, as stated. As resorcin is a toxic remedy, the larger dose might lead to trouble.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 7 TO AUGUST 13, 1888.

Lauderdale, J. V., *Major and Surgeon* (U. S. Army).—Promoted to Surgeon U. S. Army, July 28, with rank of Major, to rank from July 3, 1888.

Cowdrey, Stevens G., *Captain and Assistant Surgeon.*—Granted leave of absence for one month,—*S. O. 77, Department of Texas*, July 25, 1888.

Appel, Daniel M., *Captain and Assistant Surgeon.*—Ordered to Fort Bliss, Texas, for temporary duty.—*S. O. 77, Department of Texas*, July 25, 1888.

Mason, Charles F., *First Lieutenant and Assistant Surgeon* (U. S. Army).—Reappointed July 28, 1888, to rank from July 2, 1888. Reported for duty at Fort Washakie, Wyo., August 2, 1888

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING AUGUST 8, 1888.

Whitaker, H. W., *Passed Assistant Surgeon.*—Detached from the "Mohican," to proceed home and wait orders.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL LECTURES.

THE TREATMENT OF LUNG CAVITIES.

An Address Delivered before the Lehigh Valley Medical Association, at Easton, Pa., August 15, 1888.

BY THOMAS J. MAYS, M.D.,

PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC.

THE subject of the address which I have the honor of delivering before you to-day is that of the treatment of lung cavities. I selected this topic because the cavity-condition is so frequently met in every-day practice; and because I believe that the prevailing opinion that the cavity-stage of phthisis has, in most instances, passed beyond the bounds of human control is not only incorrect, but is prejudicial to the interests of both patient and practitioner; and I trust that before I have finished I shall be able to give you reasons for believing that patients thus affected have not necessarily passed beyond the curable stage of this disease, and that they are far better off than those suffering from an infiltration which is bound to lead up to this condition.

Let us now, at the very outset, briefly study the causes which produce and the physical features which accompany a pulmonary cavity. Probably the earliest and most direct cause of this condition, in the great majority of cases, is a proliferation and an accumulation of epithelial elements in the air cells or pulmonary alveoli—the result of a catarrhal process extending down the bronchial tubes.

On account of this rapid multiplication and accumulation of epithelial cells, the small bronchial tubes and air cells become blocked or filled up, and the whole results in a consolidation, or what is commonly called a catarrhal pneumonia. If the process of expectoration of this catarrhal material would keep pace with the rapidity of its formation, neither catarrhal pneumonia nor catarrhal phthisis could ever occur. One reason why bronchitis is a less dangerous disease than pneumonia is the fact that in the former the catarrhal secretion can be readily expelled and an accumulation avoided by the act of coughing; whilst in the latter disease, this secretion takes place so low down in the smallest bronchial ramifications and in the alveolar spaces that coughing rather serves to hinder than to enhance the process of expulsion.

In this condition, therefore, the epithelial proliferation continues, the accumulation goes on, a group of air cells here and another there clogs up and they are bound together in a mass; and the mechanical pressure thus produced gradually interferes with the vascular supply, until finally the whole affected area is entirely cut off from its source of nutrition, viz., the blood. Of course, it is quite readily conceived that if this state of things continue for any great length of time, this isolated spot must perish sooner or later; and this is precisely what happens. The moisture which it contains leaves it by diffusion, the whole becomes a comparatively dry mass of albuminous material, and now begins to undergo a cheesy degeneration. This process is analogous, in every respect, to that which takes place in the manufacture of ordinary commercial cheese. Here it is well known that before the albumen of the milk becomes cheesy, the serum must be separated from it. The cheesy nodule in the lung begins to soften from the centre to the periphery, and so soon as communication with a neighboring bronchus is secured the whole mass is expelled and a cavity is left behind.

These then are the physical features which characterize the evolution of a lung cavity in a large number of cases of pulmonary consumption. So far, the process has been purely inflammatory, and is known as the yellow or pseudo-tuberculous variety of consumption; but during caseation a specific virus is formed, which has the power of generating true tubercle; and while it is true that genuine tuberculosis accompanies and follows excavation, it is also true that it occurs less frequently, and if it does exist, is less extensive, than is usually supposed.

After a cavity is once formed, it pursues one of the following courses: (1) It may retain its original size and continue to secrete pus, and may become lined by a secreting membrane; (2) it may enlarge by further excavation of its walls or by uniting with other cavities in its immediate neighborhood; or (3) its walls may contract and its sides come together and cicatrize.

From a therapeutic point of view, which is our chief object to-day, a pulmonary cavity must be regarded in the light of two cardinal principles: (1) that it, as well as the disease of which it forms a part, is inherently a process of necrosis, or of mortification; (2) that not only its size but its existence depends on the degree of local and constitutional resistance. The growth of a lung cavity may, in all its essentials, be compared to a chronic ulcer of the lower extremity. How often do we see in these affections a conflict between healthy and diseased action? The border-line advances and recedes, making the ulcer appear large at one time and small at another, and this in direct correspondence with the local and constitutional strength or weakness of the patient. Such a course is frequently, if not universally, pursued in the formation and extension of a lung cavity. In some phthisical patients, you find that the lung tissue melts away like snow under the burning rays of a summer's sun; while in others, excavation is but slow to appear, in spite of the persistence of the disease, and if it does make itself felt, the process shows but little tendency to spread. Inquiry will probably always teach us that this difference in the liability of patients to lung cavities is owing to a difference in recuperative powers or in resistibility; that in the former instance, in all likelihood, the patient possessed a strong family history of the disease, together

with a poor appetite and a want of assimilation, while in the other, there was an absence of these conditions.

As a rule, it may be stated that a patient with a quiescent cavity is more desirable for treatment than one who has an infiltrated lung, and who is bound to pass into cavitation sooner or later. The existence of an inactive cavity, or one very nearly so, is a measure of the local resisting power of the surrounding lung tissue—it is evidence that the lung has the strength to limit the process of disintegration. There is precisely the same general condition here as is found in gangrene of an extremity. The formation of the demarcation-line shows that healthy action has successfully antagonized the march of the disease; but before this occurs there is as much uncertainty as to its point of location as there is concerning the probable size of a lung cavity after the process of destruction has once begun.

What now are the special indications which call for treatment in a patient who presents himself before you with a pulmonary cavity? They are (1) fever, (2) anorexia, (3) wasting, (4) harassing cough and expectoration, (5) loss of sleep, (6) diarrhœa, (7) hemoptysis. First in the order of importance comes fever. The degree of fever which is present in these cases depends on the activity of the process of excavation. If this has ceased and the cavity is what may be called an old one, there is very little or no fever; but it can be laid down as a rule that in all cases of phthisis pulmonalis, even in those which show an erratic, subnormal temperature, excavation is followed by a rise of temperature. With pyrexia are associated rigors, loss of weight, increased oxidation, etc. Fever in phthisis, as in fact in all other diseases, has for a long time been regarded as the result of an infective process. Without entering into an elaborate discussion of the causes and mechanism of fever, it may be stated that, according to the latest researches on this question, to which Dr. Isaac Ott, a member of this Association, has added some of the most vital contributions, the phenomenon of fever must be looked upon as one which is brought about by a disturbance of the heat-regulating centre of the nervous system; or, in other words, there is a nervous centre which presides over the evolution and dissipation of bodily heat, the same as there are nerve centres controlling motion and sensation. A disturbance of these latter centres is followed by either pain or muscular spasm, while a disturbance of the heat-centre causes a dissipation of heat. Fever is, therefore, a reflex disorder, and, according to this theory, the elevated temperature which accompanies pulmonary inflammation and excavation is due to irritation of the thermogenic nerve-centre and a consequent disturbance of the equilibrium between heat-production and heat-loss of the body.

There is little doubt, too, that the pyrexia of pulmonary phthisis is best controlled by agents which act solely through the nervous system, and this in itself is a strong confirmation of the neurotic theory of fever. Morphine, chloral, potassium bromide, chloroform and ether abolish pain and suppress muscular spasm by diminishing the impressibility of the centres of sensation and of motion. A number of our recently discovered antipyretics, such as antipyrin, antifebrin and phenacetin, bear an analogous relation to the process of fever. They reduce fever simply through their powerful influence on the nervous system.

Now all these antipyretics play an important *rôle* in the treatment of phthisical fever, yet, according to my own experience, which has been, however, rather limited so far as phenacetin is concerned, I think preference must, on the whole, be given to antipyrin. It is very soluble in water or in any aqueous vehicle, is very palatable and is therefore readily administered, which cannot be said of the other two agents. The objections to it are its expensiveness and its tendency to produce erythema of the skin in some cases if given for a protracted period. One thing must be borne in mind while giving these agents, and this is, that the ordinary small doses which are recommended, and which are usually large enough to affect the fever of acute diseases, are of very little use in the chronic fever of pulmonary phthisis. Ten or fifteen grains of antipyrin and eight or twelve grains of antifebrin or of phenacetin, every three or four hours, are small enough doses for a beginning, and must frequently be increased, probably doubled, before the fever is permanently subdued.

There can be no doubt that, aside from their antipyretic action, these agents, in virtue of their affinity for the nervous system, also exert a marked tonic influence on the whole body. In saying this I am not unmindful of the fact that when given for the purpose of lowering temperature in ordinary acute fever, they are liable to bring about sweating and depression, and at times produce a condition simulating collapse. It is needless to say, however, that such a state of affairs should never be provoked in phthisis, and furthermore that the reduction of fever can generally be secured without pushing the action of these agents to such an extreme point.

In consonance with the view that the fever of phthisis is, in some measure at least, due to the absorption of pus and other deleterious material from pulmonary cavities and bronchial tubes, the surfaces of which are in a state of catarrhal inflammation, various antiseptic agents and methods have been devised and proposed for the purpose of combating this infective fever. Medicines have been given by inhalation, by the mouth, by subcutaneous injection, as well as by enema, with this end in view; and while there can be no doubt that disinfectants applied in these ways exercise a beneficial influence on the fever, it is a question whether they do it by a process of antisepsis or by checking the local inflammation in the lungs. Among the agents which probably yield the best results when given by inhalation are ichthyol, carbolic acid and terebene. Personally I can recommend ichthyol, administered through a respirator, in the strength of a twenty-five per cent. aqueous solution. This agent is especially useful in bronchorrhœa and in actively secreting cavities, the profuse expectoration in such cases becoming remarkably diminished in a very short time.

Equal in importance to the reduction of fever is the problem of alimentation. Nothing gives rise to greater anxiety in the treatment of pulmonary phthisis than the persistent loss of appetite and wasting, nothing taxes the ingenuity of the practitioner more, and nothing demonstrates his ability better than his success in devising ways and means whereby his patient is led to partake of a sufficient amount of nourishment. This constant tendency to waste, without any effort at repair, is so great that one may be led to suspect that the real disease resides in the digestive and not in the respiratory organs. The stomach is, therefore, one of the principal battle-grounds on which the destiny of the patient has to be

fought out; and it may be laid down as a law that, if a patient improves in every respect save in eating, he must still be regarded as in a retrogressive state.

The task of making a patient eat, and frequently against his own will, is a very arduous and delicate one, but it can usually be carried out successfully, if sufficient tact is displayed by both practitioner and nurse. System, promptness and perseverance will accomplish much. A little food at regular intervals, and oft-repeated, will furnish a patient a large amount of nourishment in twenty-four hours, and will convince him that he has the power to ingest a great deal more than he thought he had. I have seen patients who, absolutely refusing all kinds of food, by persuasion, would take a glassful of milk, either cold or hot, every hour and a half or two hours, which gave them nearly two quarts of milk a day; and so soon as their confidence in their digestive capacity was restored in this way, they began to partake of other foods.

Another important feature in the dietary of a consumptive is variety. In this particular, more depends upon a good cook than on the physician or nurse. She must be dextrous and be able to render the bill of fare as tempting and as enticing as possible. The consumptive should not know in advance what the table has in store for him, so that he is not allowed sufficient time to manufacture excuses for not eating certain kinds of food. He always eats best when he is surprised by some new and inviting dish. He should also be permitted to eat anything for which he has a craving, unless it is known to be positively injurious.

In feeding these patients, it is frequently found that the first meal in the morning is vomited. This is generally due to the violent coughing efforts which are required to expel the cavity-accumulations of the previous night. This annoying factor can be overcome in most cases by asking the patient to eat nothing until the coughing paroxysm is over and the cavity cleaned out, or, if it is necessary to eat, to partake only of milk, soup, brandy or liquid food, in tablespoonful doses at intervals.

Now what kind of foods ought such patients to have? Clearly those which contain the greatest amount of food energy in the smallest bulk, and which at the same time confer the greatest amount of good on the body with the least expenditure of vital force in their digestion. Foremost among these are beef, broiled, roasted, rare or scraped; roasted lamb or mutton; eggs, raw or soft boiled; butter, cream, milk, oatmeal, beef-tea, soups, milk-punch, whiskey, brandy, wine, beef peptonoids, malted milk and other malt preparations. On the other hand, many other less nutritious foods and condiments, such as asparagus, lettuce, celery, green peas, tomatoes, potatoes, coffee, tea, chocolate, oils, spices, pepper, salt, vinegar, etc., should be admitted to the list. Meals should be served at regular intervals, five or six times a day, and the food should be slowly and thoroughly chewed before it is swallowed. Dinner taken in the middle part of the day should be the heaviest meal, and the last one at night should be the lightest one.

Feeding by the rectum is a method which deserves greater consideration in the treatment of pulmonary phthisis than it has so far received. In spite of theoretical objections, there is no question that, practically, the food which is placed in the lower bowel is digested and absorbed. This method not only economizes the strength of the stomach, but I have seen it counteract the tendency to diarrhœa which exists in many of these cases. For this purpose milk, eggs, beef essence, Valentine's meat juice, the pulp of raw fresh beef may be used. To the eggs and beef a small amount of pepsin may be added. The fluid foods are injected, while those of a semi-solid nature are best given in suppositories. One of the best ways to supply food by the rectum is to obtain hollow suppositories large enough to contain half or a whole teaspoonful of raw scraped beef-pulp, with a little pepsin, and administer them three or four times a day.

So far as medicinal treatment is concerned, much can be done to arouse and restore the digestive power of the patient. A pressure and fulness in the gastric region, associated with sour eructations after eating, is very often relieved by eight or ten drops of dilute phosphoric or of dilute nitro-muriatic acid in a glassful of hot water, after meals, or the same acids in combination with the compound tincture of cinchona, gentian and cardamom, or tincture of nux vomica, before meals.

In the next place, what can be done to quiet the distressing cough and expectoration which accompany the cavity-condition? It will, of course, be understood that the measures which have already been proposed for the reduction of fever and for the improvement of the appetite do indirectly alleviate the cough and expectoration. Cough itself is but a symptom which represents the degree of irritation wrought by the congestion, inflammation and the accumulation of catarrhal material on the terminals of the pneumogastric nerves, and anything which removes these offending causes or reduces their influence to a minimum will also ease the cough. In such a state of irritability, nothing is so soothing as the application of a large flaxseed-meal poultice to the chest. The patient soon experiences greater freedom in breathing, his cough becomes easier, the expectoration looser and a general improvement in the local condition follows. If the cough is troublesome at night, one grain of codeia can be given at bedtime, with $\frac{1}{300}$ of a grain of atropia if there is much sweating, and repeated in two or three hours if necessary. The morning cough, which persists until the cavity is cleared out, can be very much facilitated by teaching the patient to bend his head as low as possible, as if he were in the act of tying his shoes, or by asking him to go on his hands and knees, with the head lower than the buttocks. These positions, although not very æsthetic, give the law of gravity a chance to aid in the expulsion of the offensive cavity contents.

Hemoptysis is another and, sometimes, a very important and urgent symptom in the treatment of pulmonary phthisis. When I say it is important, I do not judge it so much from a material as I do from a moral standpoint. There is nothing which disturbs a patient's mental equanimity more than the spitting of blood. Its depressing effect is incalculable, yet really in ninety-five cases out of every hundred this symptom must be looked upon as a benefit rather than an injury—a relief to the congested part whence it comes, rather than a detriment to life. In the slow progress of cavity-formation, the larger bloodvessels become obliterated and disappear in the common ruin of the implicated part, and, as a rule, it is only those capillaries exposed on the surface of the excavation, similar to those often observed on the raw surface of chronic ulcers, which give rise to the bleeding. Occasionally, however, as in the rupture of an exposed aneurismal bloodvessel or in

what may be called a hemorrhagic diathesis, hemoptysis becomes, indeed, an alarming symptom; but these are the exceptions. In treating hemoptysis, give the patient as much encouragement as you possibly can. You can tell him, with perfect truthfulness, that bloodspitting is always to be expected in such a disease, that in the great majority of cases it must be regarded as a vent of nature to unload the overloaded and congested bloodvessels, and that under these conditions it is of no serious significance. Internally, give the fluid extracts of hamamelis and geranium—one part of the former to three of the latter—in teaspoonful doses every hour or two, or oftener if necessary. These agents seem to have a special control over venous hemorrhage, and they exert their styptic influence entirely independently of the tannic acid which they contain. They do not, as a rule, produce constipation, but, on the contrary, I have seen diarrhœa follow their use, which would hardly occur if their action were due to tannin; and I can further say that they succeeded in some cases in which tannic and gallic acids and ergot had failed. You will find this combination useful, too, in the hemoptysis which accompanies the early stage of the disease. Of course, if the bleeding proceeds from a large bloodvessel, absolute rest and the recumbent position must be enjoined, and ice be applied to the chest.

Last but not least in importance in treating this condition comes pulmonary gymnastics. Objections are frequently urged against this mode of expanding the lungs after cavities exist, for fear of exciting hemorrhage. While it must be admitted that this objection is not entirely without foundation, yet practically it is shown that the danger is exceedingly limited, and that the benefit which the method confers on the patient does more than compensate him for the risk which he at first incurs. It is certainly indicated. The secret why so many consumptives, even in the cavity-stage of the disease, experience such a great relief when they resort to high altitudes is that their lungs, which are habitually inactive, either from the want of exercise or from being impaired by deposits, are now immersed in a highly rarefied atmosphere which throws every available lung space into action, in order to supply the needed amount of oxygen to the body. The air cells become fully inflated, and if the products of inflammation are not dispersed, the surrounding lung tissue is kept permeable and the disease is at least kept in abeyance. Very few of these people suffer from hæmoptysis. This method of forcibly inflating the air passages of the lungs is precisely the same in principle as that which is so effectually employed by aurists in opening and in maintaining the patency of the Eustachian tube. This channel is not only made permeable by such a procedure, but its inflamed and swollen mucous membrane is restored to a more normal condition. Have we not, therefore, tangible ground for believing that that which does good in one case will also be of benefit in the other?

The breathing of compressed and of rarefied air must, therefore, be regarded as an important addition to the therapeutics of pulmonary consumption. A very simple apparatus by which air is prepared for this purpose is found in the machine with two double cylinders. With this, the patient can alternately inhale compressed and exhale into rarefied air at the same sitting. When air is breathed in this manner, there is felt during inspiration a gentle fulness and distention of the chest-cavity, while during expiration a feeling of emptiness is experienced. Waldenburg states that in this way from fifty to two hundred and fifty cubic inches more air can be inspired than during ordinary breathing. This should be done four or five times a day, or oftener if necessary, to produce the desired results.

In connection with the inhalation of compressed air, bodily exercise and forced voluntary breathing are to be highly recommended. The power of walking is common to most people, and this form of exercise is regarded of great service, even by those who exclusively advocate the high altitude treatment. Dr. Brehmer, of Görbersdorf, was, I believe, the first to prescribe for consumptives walking up a gradual ascent. A walk of half an hour or an hour, twice daily, either on the level or on a slight upward grade, is of great benefit. There are also many forms of exercise which may be carried on indoors, those performed by the arms being the most important. The arms, used as levers, are swung backward as far as possible, on a level with the shoulders, during each inspiration, and brought together, in front, during each expiration; or the hands are brought together above the head, during inspiration, and gradually brought down alongside the body, during expiration. When a deep breath is taken in accordance with either plan and held until the arms are gradually moved forward or downward, or even much longer, the process of chest expansion becomes materially enhanced. Another very effective chest exercise is to take a deep inspiration, and during expiration *only* to count in a loud voice as long as possible. A male person, with a good chest capacity, can count up to sixty or seventy, while in a female, even with good lungs, this power is somewhat reduced. Practice of this sort develops lung capacity, and the increased ability to count longer is a means whereby the improvement going on within the chest can be measured. The effects of many of these movements may be facilitated by the use of dumbbells and of chest weights.

The subject under review is a very large one, and I might and probably should have dwelt at greater length upon other methods and remedies, many of which are no doubt of much value; but my aim has been to lay only those points of treatment before you which I have tested, and which I can conscientiously recommend, and in doing this, I hope that I have been fortunate enough to impress upon you the conviction that the treatment of phthisis after it has passed into the stage of excavation is not such a formidable undertaking, is not beset by so many drawbacks as it is usually supposed to be; and I furthermore trust that I have succeeded in giving contagiousness to the feeling that no case of phthisis, unless actually moribund, should be treated with that masterly indifference which has hitherto been maintained by the profession toward this class of sufferers.

A CASE OF ABSENCE OF THE VAGINA; OPERATION.

By ARCH. DIXON, M.D.,
of Henderson, Ky.

Early in April of the present year, Miss A. L., of Webster County, Ky., aged seventeen, applied to

Dr. P. H. Griffin for relief from difficult and painful micturition. The statement of the patient was that for a long time she had been troubled in this way, the urine being voided with the greatest difficulty, it requiring from half an hour to three-quarters of an hour to empty the bladder. She had never menstruated, but had suffered with headache, pain in the back and loins, at intervals, for two years, with an occasional discharge of a few drops of bloody fluid. Examination was made by Dr. Griffin, and the discovery made that there was entire absence of the vaginal outlet; nor could any meatus urinarius be found. The same day, I saw the patient, who was a well-formed girl, of medium height and weight. The mammary glands were well developed, the pubis was covered with a rather luxuriant growth of hair, the vulva had a normal appearance, at its upper extremity the labia majora becoming attenuated an inch and a half below the pubis into a flat, smooth surface, having a cicatricial appearance. There was a rudimentary clitoris, but close inspection revealed no outlet, either urethral or vaginal. Examination per rectum demonstrated the existence of ovaries and uterus, the latter being somewhat enlarged and globular in shape.

Operation was proposed and accepted. April 17th the patient was etherized and placed in the lithotomy position; a very careful examination failed to disclose the meatus urinarius. With manipulation above the pubis and through the rectum, the bladder was compressed by Dr. John Young Brown, who succeeded in forcing a drop or two of urine through an opening so small that it was with difficulty that a very small myrtle-leaf probe could be passed into it; this was, however, accomplished, and the meatus and urethra gradually dilated until a sound could be passed into the bladder. With the index finger of the left hand in the rectum, on approximation, the tissue between the sound in the bladder and the finger was apparently not thicker than the vesico-vaginal tissue is usually found; there was no trace of a fibrous cord nor of anything indicating that a vagina had ever existed; the uterus could be distinctly felt. With the knees flexed upon the abdomen, the skin was snipped between the meatus urinarius and the anus for about an inch and a half. With the index finger of the left hand in the rectum, and the sound in the bladder for a guide, with the index finger of the right hand I rapidly succeeded in making an opening between the bladder and rectum, to the depth of three inches, when the uterus was reached; this opening was then enlarged laterally and was lengthened perhaps an inch or more, but as there had been some indication of a menstrual flow in the bloody discharge from the meatus, it was deemed best not to proceed further with the operation at this time, but to wait for the appearance of the menses, and, should they appear at the now dilated urethra, to take further steps, as might be deemed necessary. A glass plug (Sims) was placed in the newly made vagina and confined there by a T-bandage. The dilator was removed and the opening subjected to daily irrigation with carbolized water; the bladder was emptied daily by catheter.

Very little, if any, disturbance followed the operation; there was slight rise of temperature (99°) during the first three or four days, and at the end of two weeks the patient was permitted to leave her bed, with instructions to remove the plug daily and continue the irrigation. Orders were left with the nurse to inform me at once should any bloody discharge take place. On May 17th there was epistaxis with slight hematemesis, the latter due, no doubt, to the patient having swallowed the blood as it passed into the pharynx through the posterior nares; pain in the back, loins and hypogastrium was complained of, which lasted till the 21st, when a drop or two of dark blood made its appearance at the meatus. Uterine contractions were severe. The right index finger was passed into the vaginal opening and supra-pubic pressure made with the left hand; the uterus could be felt to descend and a few drops of blood were forced out through the urethral opening. A catheter was passed into the bladder and a careful search around and in the meatus revealed a minute opening at its lower border; into this a filiform bougie was carefully passed until it reached the uterus; this was followed by a uterine sound and an attempt at dilatation made, but with pain so severe that it was decided to anæsthetize the patient and proceed to dilate the canal. The opening at the lower border of the meatus yielded badly, and its lower edge was clipped with scissors and torn down with the finger; the canal was then dilated with sounds until the index finger was admitted and the cervix uteri was reached. Further dilatation was made until a Sims glass dilator would pass, pressing down the posterior tissue of the canal until the opening previously made was almost entirely closed. The retained menstrual fluid was discharged gradually for several days, when, under rather severe uterine contractions, a large discharge of black, tarry-looking blood, filled with clots, took place, since which time there has been a general improvement in the condition of the patient and she expresses herself as delighted with the ease and comfort with which she empties her bladder, and, as she expressed it, "being now made like other women."

Remarks.—The foregoing case was certainly a remarkable one in many respects, and the error committed in the management of it seems to me to be a justifiable one. After the sound was introduced into the bladder, a presumably careful and sufficient examination was made, and the conclusion arrived at that the vagina was absent and that an operation should be made. This opinion was concurred in by three other physicians. The sound glided into the bladder, as did the catheter, giving no sign of an opening save that of the urethra, nor was any suspected by me, for I gave no credence to the escape of menstrual fluid through the meatus urinarius, and should have proceeded to empty the uterus at one operation had it not been deemed best, under all the circumstances, to wait. Emmet, in speaking of such cases, says:

"The external portions of the organs of generation are generally well formed, but on exposing the vulva, the

orifice of the urethra will be found rather lower than natural, and at the bottom of a shallow sulcus, and there will be no appearance of a vaginal outlet. In absence of the vagina, the urethra is always unnaturally relaxed, but the power of retention of urine remains unimpaired."

In this case the external parts were not well formed, there was no perceptible urethral orifice, and it was only after the closest search that it could be found at all. The tissue, from the meatus to the anal orifice, was firm and smooth, with no suspicion of a vaginal outlet.

The same author further says, in regard to diagnosis:

"In congenital absence of the vagina, only a shallow sulcus is present between the labia. Some aid may be gained for forming a diagnosis from the thickness of the septum between the bladder and the rectum, and this is to be ascertained by means of a finger in the rectum and a sound in the bladder. In the congenital form, the septum will be found as thin as the recto-vesical one in the male, since there has been no development of the muscular and other tissues forming the vaginal wall. But after the vagina has been once formed and the uterus has for a while performed its functions, the vaginal wall will remain, after accidental occlusion, even thicker than before, so that there will be little difficulty in forming an opinion, even if the presence of the urethra could not be detected. Under ordinary circumstances, there can be but little difficulty in forming an accurate idea of the true condition. In the absence of a vagina, with accumulation, the condition might be complicated by the occurrence of a hematocele, or a collection of pus in the pelvis, but a careful investigation of the case will remove all such difficulties of diagnosis."

In the case under consideration there was only a shallow sulcus between the labia. With a sound in the bladder and a finger in the rectum, the septum between the bladder and rectum did not seem to be thicker than the recto-vesical septum in the male; there appeared to be an entire absence of the muscular and other tissues forming the vaginal wall; the uterus was present and enlarged, evidently from accumulation, as there was no complication in the case. Under all the circumstances, I repeat that the error committed in the management of the case seems to me to have been justified. The girl is now well and her last menstruation was normal.

Henderson, Ky., July 9, 1888.

INFLATION OF THE STOMACH WITH HYDROGEN GAS IN THE DIAGNOSIS OF WOUNDS AND PERFORATIONS OF THIS ORGAN, WITH THE REPORT OF A CASE.

By N. SENN, M.D., Ph.D.,
of Milwaukee, Wis.,
Attending Surgeon to the Milwaukee Hospital, Professor of the Principles of Surgery and Surgical Pathology in Rush Medical College, Chicago, Ill.

In my paper on "Rectal Insufflation of Hydrogen Gas as an Infallible Test in the Diagnosis of Visceral Injury of the Gastro-intestinal Canal in Penetrating Wounds of the Abdomen," read in the Surgical Section of the American Medical Association, I incidentally called the attention of the medical profession to the value of inflation of the stomach as a diagnostic measure in cases of injury or perforation of this organ, in that part of the paper which referred to inflammation of the alimentary canal through the stomach tube. We should naturally expect that the alimentary canal could be inflated with more ease and with a less degree of force by following the normal peristaltic wave. That this is not the case will be seen from the following experiments:

Experiment VII.—Dog, weight 40 pounds (18 kilograms). After complete anæsthesia was effected, a flexible rubber tube was introduced into the stomach and the free end connected by means of a rubber tube with a four-gallon rubber balloon, containing hydrogen gas. Between the gas reservoir and the stomach-tube a manometer was interposed, registering accurately the force used in making the inflation. The inflation was made by compressing the rubber bag. A tube was introduced into the rectum to facilitate the escape of gas that might reach this portion of the intestinal tract. Under a pressure of one pound and a half the stomach dilated rapidly, and later the entire abdomen became distended and resonant on percussion, but no gas escaped per rectum. When the pressure was increased to two pounds (one kilogram) no further distention of the abdomen took place, as the gas escaped along the sides of the stomach tube. At this time respiration became greatly embarrassed, but was relieved on allowing gas to escape through the stomach tube. On compressing the abdomen firmly the distention disappeared almost completely; at the same time a large quantity of gas continued to escape through the stomach tube. Inflation was renewed, and under a pressure of one pound and a half the abdomen again became uniformly distended. When the pressure was increased to two pounds (one kilogram), the dog suddenly died and all efforts at resuscitation failed. On opening the abdomen the stomach was found enormously distended, reaching three inches below the umbilicus, and occupying almost the entire abdominal cavity. The upper half of the small intestine was distended; numerous points of sharp flexions were found among the different distended coils. The distended stomach had evidently encroached so much upon the abdominal space as to render the greater part of the intestinal canal impermeable by pressure.

Experiment VIII.—Dog, weight 15 pounds. After the animal was placed fully under the influence of ether, the abdomen was opened and the cæcum and lower portion of the ileum drawn forward into the wound, and a large needle of an aspirator inserted into the ileum just above the ileo-cæcal valve. Through a rubber tube hydrogen gas was forced into the stomach. Under one pound (five hectograms) of pressure the stomach and upper portion of the intestines dilated readily. When the force was increased, the gas returned through the œsophagus along the sides of the stomach tube.

Experiment IX.—Dog, medium size. This animal was killed to ascertain the results of an experiment

made for another purpose. Rubber balloon, containing hydrogen gas, and manometer were used for making the inflation. The tube through which the inflation was made was tied in the œsophagus. The abdomen was distended enormously, and on increasing the pressure to 3¾ pounds (1½ kilograms) still no gas escaped through the rectal tube. The abdomen was then opened, when the stomach was found so enormously distended that it filled almost the entire abdominal cavity. About one-fourth of the length of the small intestine was found distended, and among the distended loops numerous acute flexions could be seen. After the abdomen was opened, under long and continuous distention, the peritoneal covering of the stomach gave way, when the manometer registered only one pound and a half of pressure.

EXPERIMENT X.—Dog, weight 18 pounds (8 kilograms). Immediately after death the œsophagus was isolated and the tube of the hydrogen gas inflator securely tied in, and a glass tube was inserted into the rectum. Under a pressure of 2¾ pounds (1.2 kilograms), registered by the manometer, the gas first dilated the stomach and then passed along the intestine until it escaped in a steady stream through the rectal tube, when it was ignited. On opening the abdomen the stomach was found greatly distended, while the distention of the intestines was a great deal less marked. None of the tunics of the stomach or intestines was injured.

EXPERIMENT XI.—Dog, weight 20 pounds (9 kilograms). Animal etherized and a flexible tube connected with the gas inflator introduced into the stomach and a glass tube into the rectum. On inflation the stomach became gradually distended, and when the pressure had reached 1½ pounds (0.6 kilogram) the dog vomited and a good deal of gas escaped at the same time. Inflation was again commenced and was followed by uniform distention and tympanites over the entire abdomen; when the pressure reached 2½ pounds (1 kilogram) the gas escaped from the rectum, and when ignited burned with a steady, blue flame. The experiment was followed by no unfavorable symptoms.

EXPERIMENT XII.—Dog, weight 12 pounds (5½ kilograms). Under the influence of ether, inflation with hydrogen gas, in the same manner as in the last experiment. As soon as the stomach became well distended and the manometer registered 1½ pounds of pressure, vomiting occurred, attended by a free escape of gas, which was followed by collapse of the distended epigastric region. When inflation was again resumed, it was noted that any increase of pressure over 1 pound (0.45 kilogram) was followed by regurgitation of gas, and, on this account, it was found impossible to inflate the lower portion of the intestinal tract. No unfavorable symptoms followed the experiment.

EXPERIMENT XIII.—Dog, weight 28 pounds (12½ kilograms). Under the influence of ether, inflation with hydrogen gas through a stomach tube. As soon as the pressure was increased to more than 1 pound (0.45 kilogram), the gas escaped along the sides of the tube through the œsophagus; consequently only the upper portion of the abdomen could be distended, and the inflation evidently did not extend much beyond the stomach. The experiment was repeated several times, with the same result. The animal remained perfectly well after the experiment.

EXPERIMENT XIV.—Dog, weight 12 pounds (5 kilograms). Inflation of stomach with hydrogen gas under full anæsthesia. The effect of the inflation was the same as in the last experiment, only the stomach and upper portion of the small intestine could be distended, and further inflation was impossible, as the gas escaped from the stomach as soon as the pressure exceeded 1 pound (0.45 kilogram). A large needle of an aspirator was passed through the linea alba into the stomach, and the gas which escaped through it, on being lighted, burned with the characteristic blue flame. After the needle was withdrawn, the inflation was continued, to ascertain if the puncture in the stomach would allow the escape of gas into the peritoneal cavity. The inflation was continued until the entire abdomen was distended by the gas. That the distention and tympanites were due to the presence of gas in the peritoneal cavity became evident, as they remained after the stomach had been emptied of its gas, and, on percussion, it was ascertained that the entire liver dulness had disappeared. The dog recovered without symptoms of peritonitis or any other ill effects from the experiment.

These experiments demonstrate conclusively that it is more difficult to inflate the alimentary canal from above downward than from below upward, as in the living animal I succeeded in only one instance in forcing hydrogen gas from the mouth to the anus, while in others a degree of force sufficient to rupture the peritoneal coat of the stomach only effected distention of the stomach and upper portion of the intestinal canal. It is evident that great distention of the stomach constitutes an important factor in causing or aggravating intestinal obstruction, as it effects compression, which again causes impermeability of the intestines, or aggravates conditions arising from an antecedent partial permeability, by producing sharp flexions among the distended coils of the intestines.

For diagnostic and surgical purposes, the stomach can be readily inflated almost to any extent through a stomach tube, and when it becomes necessary to ascertain the presence of a visceral wound or perforation of this organ, this method of inflation may be resorted to with advantage.

I have recently had an excellent opportunity to apply this test in a case of gunshot wound, of the chest and abdomen, in which, without it, it would have been impossible to make a correct diagnosis. The insufflation made the diagnosis positive, and the information obtained from it justified the treatment by laparotomy, although the general symptoms were so grave that it appeared doubtful if the patient would live long enough to complete the operation.

C. H., a man, seventy-two years of age, brought to the Milwaukee Hospital by the police patrol, at

7 A.M., July 9, 1888, for a suicidal, bulldog pistol (44-calibre) wound of the chest, inflicted about two hours previously. Pistol held in the left hand, as ascertained from the patient and confirmed subsequently by examination of the direction of the bullet. The patient stated that he had pointed the pistol toward the heart.

Examination, 7 A. M. Wound of entrance situated in the left sixth intercostal space, surrounded by emphysema. Seventh rib fractured at junction of cartilage and bone. No wound of exit. Patient conscious; complains of severe pain in the epigastric region, increased by pressure. Pulse rapid and weak. Vomits and expectorates blood. Area of liver dulness diminished. Percussion and respiratory sounds normal. No evidence of hemo- or pneumothorax.

9 A. M. Flexible tube introduced and stomach inflated with hydrogen gas from a four-gallon rubber balloon. Inflation effected by continuous pressure on the balloon. Gas escaped and ignited at the wound of entrance with an audible sound. Field of operation thoroughly disinfected. Patient etherized and laparotomy made by incision from the ensiform cartilage to the umbilicus. The omentum and stomach were drawn forward into the wound. A large perforation, about one and a half inches in length (due to the oblique direction of the bullet), was found in the stomach, midway between the pylorus and the cardiac end on the greater curvature. Stomach partially filled with coagulated blood. With the index finger introduced through this perforation, another was detected on the lesser curvature and near the cardiac end. The omentum, which was adherent to the colon, was torn through and exploration of the posterior surface of the stomach failed to reveal the old site of the second wound which was felt by the digital exploration of the interior of the organ. The blood-clots were removed from the stomach by irrigation through the lower wound.

For the purpose of locating with accuracy the second wound, the stomach was inflated through the bullet wound on the anterior surface with hydrogen gas, the escape of which made it easy to locate the second wound. The omental opening was enlarged by tearing and the perforation was discovered on the posterior surface at the lesser curvature and close to the cardiac orifice. Great difficulty was experienced in dragging the stomach sufficiently forward and downward into the abdominal incision to enable me to suture the perforation, which was two inches in length. It was closed by a continuous Lembert suture of silk, the anterior wound by a Czerny-Lembert suture.

Considerable blood was found behind the stomach, in the region of the pancreas. The hemorrhage had evidently taken place from lacerated vessels of considerable size at both perforations as well as from vessels in the pro-peritoneal space. Probable direction of the bullet from above downward, backward and to the right. At this stage collapse from shock and hemorrhage supervened. The body was partially inverted and a saline infundation of fifteen ounces of a six-tenths per cent. salt solution performed. Brandy was injected subcutaneously and faradic current applied to phrenic and pneumogastric nerves without any apparent effect. Death occurred before the abdominal wound could be closed.

The abdominal incision was sutured and inflation of hydrogen gas, per rectum, made to test the condition of the sutured stomach. A stomach tube was introduced and the gas, under a pressure of not more than a pound, forced through the entire gastro-intestinal canal, igniting and burning with a continuous flame as it escaped from the end of the stomach-tube, which showed that no gas escaped through the sutured wounds. Post-mortem was made immediately. Wound of entrance in the sixth intercostal space, seventh rib fractured at junction of cartilage and bone, both pleural cavities obliterated by adhesions, margin of lower lobe of left lung perforated, pericardium intact, lacerated opening in diaphragm admitting two fingers. Perforations in stomach as described. Liver and spleen not injured, upper margin of tail of pancreas lacerated. Bullet passed to left of the aorta, entered the left crus of the diaphragm, fractured the last rib at the neck and perforated the spinal column, entering between the last dorsal and first lumbar vertebra, escaping through the body of the latter and fracturing its right transverse process. Bullet found in the subcutaneous connective tissue of right lumbar region. The spinal canal was opened by the bullet in its passage through the vertebra, and loose fragments of bone lay in the canal. The membranes of the cord were intact and the cord itself uninjured.

The location of the wound of entrance in this case did not indicate that the bullet had entered the abdominal cavity unless the revolver was held in the left hand; in that case, as it was directed toward the heart, the track of the bullet would be necessarily downward, backward and from left to right. Taking it for granted that the bullet took this direction it would still have been possible for the stomach to escape injury. The circumscribed emphysema around the external wound and the hemoptysis, as well as the location of the wound, left no doubt that the lower lobe of the lung was injured. The absence of hemothorax and pneumothorax was explained by the post-mortem, as the left pleural cavity was found completely obliterated by adhesions. Under a pressure of not more than half a pound to the square inch, the hydrogen gas was forced through the external wound where it was lighted and burned in a large continuous flame until it was extinguished by compression with a large moist sponge. Very little gas was found in the peritoneal cavity.

In perforation of the stomach without an external wound, inflation of the organ with hydrogen gas will render the abdomen universally tympanitic, as the gas will escape into the peritoneal cavity and, as it always occupies the highest plane, on account of its low specific gravity, it will push the abdominal organs backward, and thus it happens that the liver dulness disappears completely, which fact alone, if established, makes the diagnosis of perforation posi-

tive, unless the organ is fixed in its place by peritoneal adhesions, the result of a previous peri-hepatitis.

In cases of perforating ulcer of the stomach or duodenum, if this simple diagnostic measure is resorted to in time, it will prove the means, by prompt surgical treatment, of saving many a life that has hitherto been sacrificed under the expectant plan of treatment.

It has been claimed that hydrogen gas is objectionable for purposes of inflation, as when it is mixed with a certain proportion of oxygen or atmospheric air it forms an explosive compound. Against this argument I can say that no accidents of any kind have occurred during any of my numerous experiments on animals, nor in the few cases in which it has been applied in practice. Hydrogen gas has the lowest specific gravity of all the gases known, and on this account, as well as from its non-toxic qualities, it should always be preferred to other gases and atmospheric air, simple or medicated. The hydrogen gas test appeals both to the sense of sight and hearing, if successful in cases of perforating wounds. The preparation of the gas is so simple and rapid that its use is applicable not only in hospital and city but also in country practice.

I have recently been able to make a correct diagnosis in several cases of obscure abdominal tumors, by resorting to stomach and rectal inflation of hydrogen gas, which, without these diagnostic measures, would have been impossible, short of an exploratory laparotomy. The relation of tumors of the abdominal cavity to the different organs and the peritoneal cavity can be mapped out and studied with great accuracy by dilating the stomach and different portions of the intestinal canal, at intervals, by inflation with this harmless and readily procurable gas.

SURGICAL DRAINAGE.[1]

By W. R. WHITEHEAD, M.D. (Paris),
OF DENVER, COLORADO;
EX-PRESIDENT OF THE COLORADO STATE MEDICAL SOCIETY, LATE PROFESSOR OF ANATOMY IN THE MEDICAL DEPARTMENTS OF THE STATE UNIVERSITY OF COLORADO AND OF THE UNIVERSITY OF DENVER, ETC.

More than a decade after Chassaignac had established the value of drain-tubes in the drainage of suppurating wounds, one of America's greatest surgeons[2] wrote in 1872, in his classical work on surgery, "that the great objection to drain-tubes was their liability to become clogged, and their tendency to cause irritation in the parts into which they are introduced." "For these reasons," said this eminent surgeon, "it is not likely they will ever come into general use."

Influenced by the teachings of Chassaignac, and also by the excellent results of my personal experience of the draining of suppurating wounds, I became an advocate of surgical drainage. Now that the principles of aseptic and antiseptic surgery are so well known, and are so thoroughly appreciated, I am more impressed than ever with the value of surgical drainage; and propose, in a brief communication on this important subject, to endeavor to claim for it the attention it deserves.

My first personal trial of drain-tubes was in 1860, when I used them, conjointly with tonics and cod-liver oil, in a case of scrofulous osteitis of the scapula: A counter-opening was made so as to pass in a perforated rubber tube, and permit the two ends of this tube to be tied together on the outside, after Chassaignac's method. The tube was syringed out daily, so as to keep it clear, and the wound thus cleansed with a solution of chlorinated soda, or Labarraque's disinfecting liquid. Occasionally, the tube was removed, cleaned and reinserted. The improvement in the local condition was marvellous. Subsequently, and during the early part of our civil war, as a surgeon in the Confederate army, I used surgical drainage in a number of suppurating wounds; and, notably, in one case of phlegmon of the neck, which succeeded to a gunshot wound that cut the cervical plexus: I incised the deep cervical fascia and, having made suitable counter-openings, inserted two rubber drain tubes, and tied their ends together as just described; and, as well as I can now remember, I treated the case in much the same way as the case first mentioned. After some weeks the wound entirely healed, the general health improved and there remained only the paralysis of the upper limb.

It is, however, of drainage as practised at the present time that I wish to speak; and as nothing so vividly and forcibly impresses my own mind as the practical application of a method, I shall, therefore, beg to call attention to the following recent case of fracture of the skull in which, I believe, the drainage, under an aseptic management of the wound, was the most interesting and important feature of the treatment.

Case.—Horace C., aged five and a half years, on the evening of April 22, 1888, while crawling near a horse, received a kick, which fractured the frontal bone on the left side, the fracture extending to the coronal suture. The depressed piece of bone was nearest to this suture, and the depression corresponded to a line extending obliquely downward, forward and outward from the coronal suture to the temporal ridge and slightly posterior to the external angular process of the frontal bone. The depressed edge of the fractured bone was to the outer side of the line of fracture. The depression did not give rise to any cerebral disturbances affecting consciousness, or causing motor paralysis.[1]

[1] Read before the Colorado State Medical Society, June, 1888.

[2] Gross: System of Surgery, vol. i. p. 487.

[1] The line of fracture crossed the horizontal convolutions of the frontal lobe anterior to the ascending frontal and parietal convolutions or motor areas of the cortex. I thought best to trephine,

His head having been shaved he was chloroformed by Dr. J. E. Lowery, of Denver. An incision was made at right angles to the lacerated cut, and under thorough aseptic precautions the head was trephined, and the depressed piece of bone elevated with the point of a Sayre's periosteotome; the depressed piece of bone returning to its place with a sudden and quite audible snap. The wound was sutured with catgut, and a small rubber drain-tube placed in the centre of the wound, opposite the button of bone removed (see A in the wood-cut), and a still smaller tube was placed in the posterior angle of the wound. Both

Fig. 1.

Case of trephining for fracture of the skull; illustrating the value of drainage.

drain-tubes were secured in place, each with a stitch of catgut; a slightly moist iodoform gauze dressing was applied immediately over the wound; over this dressing was placed a small piece of folded sublimate gauze, and over this a circular piece of very thin rubber tissue cloth, and overlapping the rubber on all sides for several inches I placed a dressing of borated cotton, and applied a double-headed bandage, securing it under the chin, not having with me any elastic bands.

I think the drain-tubes were of major importance, as the dressing when removed plainly showed. If pus forms and burrows beneath the skull, a case like this becomes very serious, and the most rigorous antisepticism will be attended with doubtful results. The temperature averaged 99° to 101° F.

April 30, I removed the dressings, they having become loose, the fault of not having elastic bands with me when they were applied. Wound healed, except at drain holes; removing the tubes, there was a drop or two of pus. The wound had evidently remained aseptic until the fifth or sixth day, when the dressing became loose during the night; hence the pus. After syringing the drain holes with a mercuric bichloride solution, they were stuffed with iodoform gauze and dressed. This was repeated once or twice only, when the wound healed.

On removing the first dressing, the borated cotton, all around the outside of the rubber tissue cloth, was thickly saturated with dry blood. Thus it is seen how effectively the little drain-tubes performed their first office of draining off the blood and serum within the first few hours. No blood clot was left within the wound to become disorganized, should its aseptic condition fail to be maintained a sufficient length of time; but the drain-tubes were in place and ready, if needed, to perform their second office of draining off pus.

Healing, with a view to an organization of the moist blood clot, or after Schede's method, would have required the most scrupulous care in the adjustment of bandages about the head to keep them from becoming loose. This could have been accomplished by the use of elastic bands, in addition to the double-headed bandage, or by a suitably fitting cap.

The accompanying picture of the boy shows the scars, indicating the location of the injury; and shows, in part only, the extent of the fracture downward and outward. The dark spot in the line of the scar corresponds to the site of the trephining; and the scar to the right of this spot to the cut I made for room to apply the trephine.

There are two distinct indications which call for the use of drainage: One is to rid a fresh wound of discharges of serum and of blood within the first few hours; and the other is to prevent, subsequently, the occurrence and spread of suppuration, should it take place, or to drain a part of pus when it has already formed, just as the drain hole in the bottom of a flower-pot prevents a saturated condition of the soil about the roots of a plant.

It was for the purpose of draining pus, and for it alone, that drainage was originally employed in the days of preaseptic surgery.

I formerly used a well-known antiseptic wash, Labarraque's solution, already mentioned, for wash-

because under careful asepsis and skilful management of the case, the dangers of trephining are greatly less than the subsequent dangers of cerebral disturbance from a neglect to elevate the depressed bone. The button of bone was not returned, because it was small, and the small opening permitted the use of a drain-tube, a consideration infinitely more important than the complete occlusion of the line of fracture, because the blood which escaped in the dressing through the drain-tube would otherwise have given rise to compression. When the quantity of bone removed by the trephine is considerable, it is best, under aseptic precautions, to return most of it, as there will be, probably, openings enough for drain-tubes.

ing out wounds through drain-tubes. It seems so rational to do so that I have no doubt that centuries ago the thought must have occurred to surgeons to drain and wash out suppurating wounds; only the example was wanting, and the present kinds of cheap drains were not to be had.

The progress of surgery has heretofore been slow, like that of other arts which depend upon the gradual adoption and use of the numerous conveniences of life, which suggest the use of other conveniences.

The spirit of conservatism often retards the adoption of a really good thing, and will not permit us to live ahead of our time. Conservatism holds the world in check, until the world, generally, is ready to approve and accept of a new thing. Drainage had been waiting for the surgical era of Listerism, when it could accomplish its grandest triumphs.

The distinguished preaseptic surgeon, already mentioned, the pride of the surgical profession of America, wrote his disapproval of drainage; and at once the spirit of conservatism, so eminently respectable and so conspicuously shown, discarded the new method of Chassaignac; but it has reappeared at the front, reinforced by aseptic and antiseptic methods, and, I believe, to stay for a while until something better supersedes it.

Drain-tubes made of aluminium and of glass are used to meet special indications. Silver, especially, has been used, and, probably, was the first substance employed for this purpose. Thin sheet lead, made into tubes, is an available material, out of which drain-tubes have been made.[1] Catgut, or rather sheepgut, bunched in numerous strands, as also horse-hairs arranged in a similar manner, are much praised by some surgeons. John Chiene, of Edinburg, was the first to propose catgut as a drain. The well-known objection to this material is its property to absorb moisture and swell rapidly if previously put in an aqueous solution, making it difficult to thread a needle with it; and when used for drainage, catgut softens, swells and obstructs the flow of blood and serum, unless hardened beforehand in a chromic acid solution, so that filtration by capillarity along the threads is prevented. It is only during the first few hours that this kind of drain is available. It will not drain pus at all. If employed, it should be collected into a bundle of threads, of from five to twenty pieces, tied in the middle with a single catgut thread, and this should be threaded to a needle, and the drain stitched to the bottom of the wound, to keep it in place; besides, the catgut should be chromicised. The catgut drain is an absorbable drain, and, after a variable period, disappears. Those hardened in chromic acid take a great while to be absorbed. Horse-hair is an available substance for draining wounds; a bundle of horse-hairs is previously made aseptic, and tied in the middle with a carbolized silk thread; the knotted central part is placed in the wound by means of a fistula forceps. Horse-hair is not absorbable.

Neuber, of Kiel, was the first to use absorbable drain tubes, made from the tibiæ of oxen and decalcified. Macewen first used the long bones of chickens for the same purpose. Those which I use are prepared by myself, after Kocher's method; they are the long bones of chickens, decalcified, scraped and cleaned, and after remaining in the oil of juniper berries forty-eight hours, are then placed in strong alcohol, in which they are preserved ready for use. Red rubber drain-tubes, of different sizes, are also sometimes used. It is desirable to employ rubber tubes free from sulphur, when these are used. The red rubber is said not to contain any sulphur.

When a fresh wound is made thoroughly aseptic, and it can be confidently assumed that suppuration will be prevented, then I know of no better drain than a non-chromicised and properly prepared bone drain-tube, which will, probably, be absorbed within eight to ten days. After some recent joint resections, I have found bone drain-tubes, of my own preparation, to disappear within that period; these were cases in which I also used, at least, one rubber tube, at the most dependent part of the wounds; and these cases, with others, will form the subject of a future paper, but not, however, with any especial reference to drainage. In one of two cases of partial resection of the knee-joint, the joint resection was perfectly healed within a month; but two of the drainage tube holes continued to discharge pus, and required free incision and scraping, which was done under chloroform given by Dr. Lowery, when, after a few weeks, the wounds were entirely healed. The peculiar feature of this case with reference to the drainage, and which is appositely cited here, was that some weeks before, I curetted the suppurating drain holes, one of which I laid bare by incision. Around the orifices of the drain holes, there were granulating ulcerations, which, as Gerster observes, are an unmistakable indication for the use of the curette or sharp spoon.

In my opinion, the best drain-tube for general use is the perforated rubber tube of medium size. I believe it is better to insert one or more small tubes, side by side, than to use a very large tube, especially in the aseptic treatment of wounds; because one tube can be removed on the third or fourth day, if required; and if they should all remain for ten days or longer before removal, and the wound remains aseptic during this time, they can then be taken out, and there will not be found a drop of pus. Afterward, under proper care, the drain holes close with-

[1] Dr. Buckingham, of our Society, saw such used forty years ago.

out suppuration, unless there remains a focus of cheesy-like degeneration, which was the cause of the persistent suppuration from the drain holes in the case just mentioned, and which was, finally, completely cured by scraping and subsequent dressing with iodoform gauze.

A good way to treat a suppurating sinus after the drain-tube is removed and the sinus shows no tendency to heal completely is to benumb the parts around the orifice of the sinus with a ten per cent. solution of muriate of cocaine, then to make a slight incision over the sinus, curette it and dress it with iodoform gauze in the following manner: Take a small strip of bichloride gauze, or simply iodoform gauze, dust it thickly with iodoform, roll and twist it into a cord: seize the cord near its middle with a fistula forceps and carry it to the bottom of the wound or sinus, letting the ends of the cord project from the cut; dust thickly with iodoform and complete the dressing. This cord thickly impregnated with iodoform checks suppuration, and also acts, to some extent, like a drain; only infrequent dressings are needed, and the sinus heals rapidly, especially if it has been curetted. Small safety pins are used to prevent drain-tubes from slipping into the wound; but I have found it more convenient to stitch each one of them to the skin with a single loop of fine catgut: this prevents them from slipping in or out: and if there is no occasion to remove the drain-tubes before the eighth or tenth day, the catgut is absorbed, as is also the drain-tube, if it be a bone drain-tube, well prepared and not chromicised. If the tube be a rubber one, it is readily removed, and if found aseptic, or without pus following it, the hole should be dressed with iodoform, without syringing it out, as the syringing is apt to break up the newly formed adhesions.

In making a counter-opening for a drain-tube, there are two ways to do this. If it is a phlegmon to be drained, incise it, introduce the index finger of the left hand and seek for the most dependent part of the abscess cavity, push firmly with this finger and cut the skin over it; then push through this cut with the closed blunt points of the fistula forceps, seize the tube with the forceps and pull it into the cavity. If, instead of a phlegmon to be opened and then drained, there is pus escaping from a sinus, badly situated for drainage, it is, of course, necessary to make a counter-opening. In this case, probe the sinus with the closed fistula forceps, seek the place where the counter-opening is to be made, push with a drilling motion the points of the closed forceps toward the skin, and when the skin is reached incise and draw the drain-tube through. This, I believe, is Lister's plan, and avoids a large cut.

OPERATION FOR INGROWING TOE-NAIL, WITH HYPODERMATIC INJECTION OF COCAINE, FOLLOWED BY COLLAPSE AND GANGRENE.

By F. JOHNSTON, M.D.,
of Cairo, Georgia.

Miss S., æt. twenty, single, in good health, consulted me, June 25th, complaining of pain in the great toe of her left foot. On examination, I discovered that the nail had grown to a depth of an eighth of an inch in the soft parts on the inner side; otherwise, the toe appeared normal. I advised a V-shaped operation, which I performed the next day as follows:

After thoroughly washing the left foot with warm water and soap, and disinfecting all instruments that were to be used, I inserted one-half grain of muriate of cocaine, with an ordinary hypodermatic syringe, in the soft parts on the inner side of the great toe. After waiting two minutes, I ascertained that feeling in the parts was completely absent. I made a V-shaped incision, nearly to the bone, and took out the plug. As soon as hemorrhage was arrested, which was very slight, the two raw surfaces were brought together and five silk sutures, previously soaked in a twenty per cent. solution of carbolic acid, were used. The wound was then dressed by sprinkling iodoform on it, and soft linen used as a bandage, the foot being kept in an elevated position.

From the time of the injection of cocaine till the completion of the operation was thirty-five minutes, and during that time she complained of no pain at all. Just as I was preparing to leave, I saw she was in a state of collapse, pulseless, lips cyanosed and heart beating feebly and irregularly. I administered nearly a drachm of sulphuric ether hypodermatically, and two drops of nitrite of amyl internally, which gave immediate relief.

I visited my patient on the following morning and found her resting well, complaining but little. I then took off the dressing to put on a new one, and to my complete astonishment the entire flesh on the inner side of the toe was black, cold and bloodless, and had a mummified look. The stitches were all taken out, and the wound treated as gangrenous, and in two weeks' time her toe was well and she was able to walk without further pain.

MEDICAL PROGRESS.

Treatment of Yellow Fever.—Regarding the treatment of this disease, Dr. George M. Sternberg, U. S. A., in the *Therapeutic Gazette*, August 15, 1888, reports the favorable results obtained in a series of twelve cases treated on the alkaline plan.

His recent researches in Havana have led him to think it very probable that in yellow fever, as in cholera, the specific microörganism causing the disease is located in the alimentary canal. While this is not proved, it is demonstrated that, as a rule, no microörganism capable of development in the culture-media usually employed by bacteriologists, is present in the blood or tissues of those recently dead from yellow fever. This view naturally suggests intestinal antisepsis as a mode of treatment.

It is well known that in yellow fever the urine and the vomited matters are highly acid. He has also found the intestinal contents to have usually a more or less decided acid reaction. A microbe, therefore, capable of multiplying in the stomach and intestine in this disease must be able to grow in an acid medium. But aside from this theoretical reason for prescribing alkalies, the highly acid condition of the secretions furnishes an indication for such a treatment, and the writer has long desired an opportunity to see a thorough trial of a decidedly alkaline treatment.

These considerations induced him during his recent visit to Havana to propose the following formula:

℞.—Sodii bicarb., grammes x (gr. 150);
Hydrarg. chlorid. corrosiv., centigrammes ij (gr. ⅓);
Aquæ puræ, litre j (1 quart).—M.

Sig.—50 grammes (about 1¾ oz.) every hour; to be given *ice cold*.

This treatment was adopted by Dr. Raphael Weiss, house physician at the Garcini Hospital, and he has just received from him a record of twelve cases treated by the director of the hospital, Dr. Francis Cabera, and himself.

It will be seen that they all recovered, and he adds that every case so far treated at the Garcini by that method has recovered. While these twelve cases were being treated, and a little before, eight cases were treated in the same institution by other methods, and five of the eight died.

Dr. Weiss writes him that in some of the more severe cases he increased the amount of bichloride to five centigrammes (¾ gr.) per litre. He says:

"Administering to the sick the bichloride of mercury, according to your directions, the gastric phenomena are very much modified; the gastric sediments appear later, and in no case have they been entirely dark. In some cases, truly dangerous on account of the state of the patient, in a general sense, gastric sediments (black vomit) did not appear, nor even nausea. The pains in the stomach were not so severe."

In some of the cases Dr. Weiss added benzoate of sodium to the formula for its laxative effect, and administered daily two enemas containing each a gramme (15 grs.) of the phenate of sodium.

Sherry wine and hypodermatic injections of ether were given during the second stage, when the pulse was feeble and the condition of the patient seemed to call for a stimulant.

With reference to the urinary secretion, Dr. Weiss writes:

"The urine has always been abundant. In some cases the density lowered, but was compensated by a large quantity of urine. Albumin did not appear in some of the cases, in others the amount was small, and in others it reached two grammes to the litre. The albumin has always disappeared on the second or third day, and then the fever ceased."

Whether the favorable results are to be ascribed to the alkali, or to the antiseptic action of the bichloride, can only be determined by testing the two remedies separately; but he is very much disposed to ascribe the unusual absence of gastric disturbance, and the abundant secretion of urine noted, to the alkaline element of the treatment, and it is extremely doubtful whether the bichloride reaches the intestine in sufficient quantity to exercise any decided antiseptic effect in that portion of the alimentary canal. The bicarbonate should be free from carbonate of sodium, as the mercuric chloride is decomposed by this salt and by alkalies generally. It is possible that the biniodide might be substituted to advantage in the formula above given.

In some experiments made by him several years since to determine the comparative antiseptic value of the salts and oxides of mercury, the following results were obtained:

	Active.	Failed
Biniodide of mercury . .	1 to 20,000	1 to 40,000
Bichloride of mercury . .	1 to 15,000	1 to 20,000
Protoidide of mercury .	1 to 10,000	1 to 20,000
Yellow oxide of mercury .	1 to 1,000	1 to 2,000
Black oxide of mercury .	1 to 500	1 to 1,000
Calomel	.....	1 to 100
Blue mass	.....	1 to 100

The bichloride, the biniodide and the oxides of mercury exhibit a decided inhibitory—antiseptic—effect upon the development of the bacteria of putrefaction in the proportion given in the second column, and we may use these figures as a guide in our efforts to secure intestinal antisepsis by means of these agents; although it is, of course, very uncertain how much of the soluble mercuric salt introduced into the stomach reaches the intestine in an active form—probably very little. In the formula which he gave to the physicians of the Garcini Hospital the amount of bichloride prescribed is really only in the proportion of 1 to 50,000 parts of the solution; but he considered it advisable to commence the treatment with an amount that was entirely safe, and to increase the dose afterward if it was found to be prudent and desirable to do so. Dr. Weiss has, in fact, increased the dose in several severe cases to 5 centigrammes per litre—1 to 20,000. As all of these cases recovered, we may infer that when largely diluted, as in this formula, and given in small quantities at short intervals, it may be safely administered in these doses; but, as already intimated, he is rather disposed to attribute the favorable course of the disease to the full alkaline treatment than to any antiseptic effect of the bichloride in the intestine. In the stomach, however, he would expect a decided antiseptic effect from the medicine as administered; and perhaps this is, after all, what is most needed.

Cocaine as a Means of Diagnosis in Laryngeal Maladies.—One of the most difficult points in laryngeal diseases is the diagnosis of the cause of œdematous infiltration, which may be due to tuberculous, syphilitic or cancerous origin. Oftentimes the general history gives no clue. In such cases cocaine proves of value; if a solution is applied to the swollen membrane and causes the congestion to disappear, it may be assumed that the cause is a simple catarrh.

If, however, the redness persists after repeated applications, the trouble is probably excited by elements of a more serious import.—*Revue de Thérapeutique*, August 1, 1888.

Epistaxis in Nephritis.—M. Gaucher considers persistent epistaxis an important symptom in early interstitial nephritis, especially in alcoholic subjects.—*Revue de Thérapeutique*, August 1, 1888.

Calomel in Tuberculous Processes.—Dr. G. Martell, of Breslau (*Prag. med. Woch.*, No. 25), has for three years studied the action of calomel upon tuberculous processes, and has come to the conclusion that it must be recognized as the best adapted specific antiseptic in the treatment of tuberculous conditions. With proper precautions, its use should not give rise to toxic manifestations. By the introduction of calomel, the use of mercury against internal tuberculous processes, particularly in the lungs, is made possible. Dusted on external tuberculous processes, it acts locally; inhaled, in pulmonary tuberculosis, by contact with the diseased textures. Calomel, given in powder, is also useful in tuberculous ulceration of the intestine; in the form of a soap, it is also efficient in tuberculous glandular enlargement. The author concludes this prefatory publication with the statement that he has had such good results from the use of calomel in tuberculous processes that he wishes clinical confirmation of his recommendation before proceeding with more extended observations.—*Wiener medizin. Wochenschr.*, July 1, 1888.

Electricity in Incontinence of Urine.—In the *Gaceta de Enfermedades de los Organes Genito-Urinarios* for May, Dr. Alejandro Settier records two cases of complete incontinence of urine in which he used electrical treatment with success. The first patient was an officer, aged twenty-seven years, who had suffered from the infirmity for eight years; it dated from a time when he was kept under arrest for nine hours without being able to pass water. The urine dribbled away in small quantities every few minutes without his being conscious of the fact; he only knew that it had occurred by feeling wet. Belladonna, atropine and nux vomica had been given without effect. Electricity was applied in the manner recommended by Guyon, and in little more than three weeks the patient was able to hold his water for half an hour. After some months of persevering treatment he could retain his water for two hours during the day and only required to be awakened once in the night. Beyond this point, however, no further improvement could be obtained. The second patient was a boy, aged seven years, in whom the affection appeared to date almost from birth. The same treatment was employed, and in rather less than two months the little patient could control his bladder for thirty-five minutes, and, finally, was completely cured. Dr. Settier lays stress on the importance of continuing the treatment at short intervals for a considerable time after the bladder has recovered its tonicity.—*British Medical Journal*, July 28, 1888.

Injection of Iodoformized Ether in Abscesses.—M. Verneuil objects to the very large dose, one hundred grammes, of this solution into a suppurating cavity, and thinks the amount should be apportioned to each case. He has used it extensively with good results, and does not think it causes vomiting; but thinks that due to visceral affections, which have been shown to exist at the autopsies of all those cases in which vomiting was a prominent symptom.—*L'Abeille Médicale*, July 16, 1888.

Leiter's Tubes as a Sleep-producing Means.—Loebl (*Wiener medizin. Presse*) has within a short time advised three patients who complained of attacks of vertigo and fainting, of feelings of traction in the occipital region, of sensations of constriction about the head, to apply Leiter's tubes to the head nightly for an hour before going to bed. Each, independently of the others, in the course of some time, reported that the symptoms for which the apparatus was applied had only partly disappeared, but that sleep had been favorably influenced. One, a female, in whom the dizziness had not entirely gone but occurred more rarely than before, could not find words enough to express her gratification that sleep, which, for a long time, had been disturbed, was now deeper and lasted longer. The author was of the view that the rest, the horizontal position, the concentration of the attention upon the working of the apparatus for a short time had a *quasi* hypnotic influence. The patient, a woman of education, opposed this view, saying that during the application of the apparatus she had her attendant read to her, so that her attention was directed to the reading and not to the apparatus.—*Memorabilien*, July 6, 1888; from *Centralblatt für die gesammte Therapie*, 1888.

Varicose Tumor of Lid.—Chisolm reports a peculiar case occurring in a man of fifty-nine years. When he looks downward for a very short time, as when occupied in tying his shoe strings, seeking some small object on the floor, or in looking into his plate during a meal, the lower lid of the left eye rapidly swells until it attains the size of a small fowl's egg, encroaching upon the palpebral split, and temporarily shutting in the sight. When the head is lifted the swelling rapidly disappears. While the lid is enlarging the patient experiences the sensation of a warm current of liquid in the lid accompanied by a feeling of distention, but not of pain.

The surgical procedure by which a cure was effected was as follows: When the sac was most distended, a heavy seton composed of several strands of silk thread was passed through the whole length of the sac. The presence of this foreign body was designed to excite plastic inflammation in the lining surfaces of the venous sac. By the end of the fourth day there seemed to be much thickening of the skin, and the presumption was that plastic inflammation had been excited. With the seton left *in situ* the opposing walls of the sac were clamped together by passing three double sutures from the inner face of the lid through the tumor. The threads were secured over a roll of sponge which made direct pressure over the whole outer face of the lid. In passing these lid sutures each thread had two needles, one on each end of the thread. By passing one needle through the upper part of the lid and the other deep in the cul-de-sac, when the two ends of the thread as they appeared upon the face were firmly tied over the sponge, the clamp of thread on the conjunctiva within and the sponge without brought the whole opposing surfaces of the flattened tumor in contact and insured the complete obliteration of the sac. The presence of these three sutures with the sponge caused so much pain and inflam-

mation, with excessive chemosis, that they were removed with the seton on the third day. The swelling rapidly subsided upon the withdrawal of the threads. A week afterward the patient was dismissed with the inflammatory swelling nearly effaced.

The patient was heard from six weeks after the operation. The inflammatory thickening of the lid had altogether disappeared, and with it all trace of the swelling. The obliteration of the sac remains permanent.—*Archives of Ophthalmology*, June, 1888.

Endometritis.—Dumontpallier treats this affection by tampons saturated in zinc chloride solution and applied to the cavity of the uterus. He maintains the position of the uterus by pressure on the hypogastrium, and inserts the tampon, on a piece of whalebone, with a spiral motion. The pain does not commence directly, and only continues for a few moments. He reports most happy results.—*Gazette Médicale de Paris*, Aug. 4, 1888.

For the Gastro-intestinal Catarrh of Children the following formula is recommended (Lem. méd.):

Bismuth. salicylat. . .	4 to 5 parts.
Glycerin	10 to 20 parts.
Aquæ	100 parts.—M.

S. A tea or tablespoonful, according to age, every four hours.—*Deutsch. medicin. Wochenschr.*, July 26, 1888.

Pelvic Abscess Treated by Trephining.—Adding to the literature of these cases, the first of which was performed by Fischer, Hanover, in 1880, Dr. Rinne presents two cases of his own (*Archiv für klin. Chirurg.*, Bd. xxxiv. Heft. 4). In both of them he obtained favorable results. That occurring in a boy of nineteen years was first supposed to be coxalgia; but the excessive pain, high fever and, later on, the appearance of a fistula convinced him that the case was one of pelvic abscess. A transverse incision was made first above the greater trochanter, the periosteum opened by a crucial incision and the bone trephined. The finger introduced into the opening found the large cavity completely filled with pus, and masses of granulations which were removed by curetting. The inner surface of the ilium was covered with a soft granulating tissue, but no necrosis was discovered. Free drainage was established and over half a litre of pus was evacuated. The patient made a complete recovery in nine weeks.

The other case was treated in the same way, save that antiseptic precautions were more rigidly enforced and the bone opening was about the size of a *franc*. Notwithstanding that both cases had been of long duration, the bony tissue was not involved.

Cocaine as an Antiseptic.—Based on the antiseptic properties of cocaine taken internally, Luton (*Rev. gén. de clin. et de Thér.*, No. 4) has successfully used this remedy in variola. He thus sums up: 1. Cocaine used at the beginning of the disease notably lowers the temperature (from 104.9° to 98.6° in twenty-four hours). 2. At the same time, the eruption is checked and does not advance. 3. Given in the eruptive stage, cocaine is abortifacient; the pustules desiccate. 4. If the administration is stopped at this stage, the disease resumes its usual course, the temperature rises again, and the eruption pursues its normal sequence. 5. The treatment consists in the subcutaneous injection of four minims of a twenty per cent. solution, three or four times daily, and the internal administration of a solution of three and one-half grains of cocaine in four ounces of gum mixture, in tablespoonful doses.—*Deutsch. medicinische Wochenschrift*, July 12, 1888; from *Wiener medizin. Presse*, 1888, No. 12.

Salicylate of Sodium for Toothache.—Hofmann (*Prag. medizin. Wochenschr.*, No. 11, 1888) recommends salicylate of sodium as an internal remedy for toothache. The relief, however, is only temporary. The pain returns unless the cause is removed. Twelve grains are given at intervals of half an hour; as a rule, two to three doses suffice to allay the pain for one or more days.

The Administration of Turpentine.— The more extended use of turpentine as a medicament is handicapped by the unpleasantness of the remedy. There is no difficulty in the inhalation of the oil. A compress saturated with half an ounce held to the nose or placed on the pillow at night suffices for several hours. The internal administration, however, is more difficult. To overcome this objectionable feature, Frölich (*Deutsch. medizin. Wochenschr.*, July 19) has had made lozenges containing each 1½ and 3 drops of rectified oil of turpentine in combination with sugar. By this means the remedy is brought into direct contact with the mucous membrane, so increasing its efficacy.

The Local Treatment of Diseases of the Bladder.—Ultzmann considers topical treatment admissible only in chronic disorders of the bladder and the posterior portion of the urethra, and, as is not uncommon in gonorrhœa, these parts often require local treatment. For this purpose a thin catheter is passed into the bladder and then withdrawn until the flow of fluid ceases—the beak of the instrument thus lying at the neck of the bladder. If about ten ounces of an antiseptic fluid are now slowly injected, it will gradually flow over the diseased mucous membrane into the bladder, to be spontaneously evacuated by the patient after the removal of the catheter. In the treatment of the bladder itself, Ultzmann rejects the double current, because independently of the cases with shrinking of the bladder, the mucous membrane of the contracted organ is only partially washed. He prefers washing out the bladder by means of a soft catheter and a hand syringe, qualifying that the fluid must be completely evacuated. Ultzmann uses weak solutions, *e.g.*, one-sixteenth per cent. carbolic acid, one-half per cent. resorcin, one-tenth per cent. permanganate of potassium; in case of ammoniacal fermentation, he uses three drops of amyl hydride to a pint of water; in case of phosphaturia a one-tenth per cent. salicylic solution.—*Deutsch. medicin. Wochenschr.*, August 2.

Treatment of Diphtheria.—Couset, of Brussels, strongly urges the use of a mixture of tannin, mucilage and alcohol for local application. He applies it by means of a syringe and claims that the mucilage acts as a protection and keeps the ingredients longer in contact with the diseased surface. He cites a long series of cases which show the efficiency of his plan.—*Journal de Méd. et Chir. Pratiques*, August 4, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 25, 1888.

THE PRESENT STATUS OF THE IMPROVED CÆSAREAN OPERATION.

IN view of the fact that important Cæsarean successes are to be reported before the American Gynecological Society at its meeting next month in Washington, and the merits of the new method of operating fully discussed, we have thought it well to prepare some pertinent statements bearing upon the subject to be considered. As this society has in its active membership fourteen Cæsareanists, who during the past forty-one years have collectively performed twenty *gastro-hysterotomies*, twelve of them by the new or Sänger method; and its members have also performed nine of the fourteen *laparo-elytrotomies* upon record, we may expect the whole Cæsarean subject to be ably considered. Five operations under the improved method, performed by three members, with four recoveries, one case having been entirely hopeless, are yet to be reported.

Perhaps there are not five men in all Europe and America who know to what extent the improved operation has been performed, and how successful its results have been, in the hands of those engaged in it. We have noticed very erroneous statements made in regard to it before medical bodies, not the least of which is, that it owes its marvellous results to its having fallen into the hands of a few very skilful men. Now so far is this from being the case, that the 131 operations in our record have been the collective work of 73 men, in Germany, America, Austria, Italy, Russia, Switzerland, Holland, France, England, India and Denmark. It is true that Prof. Leopold, of Dresden, has had fourteen cases with only two deaths, and that Prof. Schauta, of Prague, formerly of Innsbruck, has operated six times without a death; but take the work of last year, 1887, in which Leopold had three operations without a death, and Zweifel five operations with one death, and we find a record of 44 cases under 34 operators, with only 9 deaths. There were 29 operations divided among as many operators, with a saving of $72\frac{12}{29}$ per cent. of the women, which is about equal to the general average of 95, saved out of the whole 131 cases.

The Dresden Maternity has had 20 operations, with but 2 deaths, under three operators, counting respectively 14, 5 and 1 each. The Leipzig Cæsareanists have a credit of 16 cases under six operators, or respectively 5, 5, 2, 2, 1, 1 each, with 2 deaths. These have been, until the present year, the special centres of the new operation; but Vienna promises to take the leading position, as she did through the obstetrical staff of her Krankenhaus, under the Porro operation, having already had seven cases this year, as far as heard from, under three operators, without a death. Beginners have much to encourage them in the records of the past, as *first* operations have been successfully performed in 47 out of 73 cases; and had not many of these cases been very unfavorable, or actually hopeless, the proportion might have been higher; and this is specially true of our own country. Skill in abdominal surgery and a thorough knowledge of, and adherence to the technique, with a fair case in hand, are the chief requisites for success. Drs. Zweifel, Paul Bar and Weber all lost their second cases after saving the first; Dr. Chiara lost his third, and Leopold his fourth.

The deaths after the Sänger-Cæsarean operation are to be considered under four heads, viz., 1. Those resulting from a preëxisting and hopeless disease, such as the last stages of cancer, Bright's kidney or cardiac lesions. 2. Those resulting indirectly from the operation, because of the physical exhaustion of the patient, the effects of long labor; or produced by futile attempts to deliver with the forceps, by version, or by craniotomy. 3. Those resulting from the parturient state, rather than the operation, as from diphtheritic endometritis or other *post-partum* disease, endemic in a hospital. And 4. Those the direct result of the operation in favorable subjects.

Peritonitis after a Cæsarean section is not necessarily a consequence of it; but may be entirely in-

dependent of it, as was the case with the third patient of Prof. Chiara, of Florence, operated upon on January 5, 1888. On the sixth day she bid fair to recover, as his first and second cases had done: on the seventh, violent peritonitis occurred, and on the eighth day she died. An autopsy showed that the woman had been the subject of ulcerative enteritis, presenting old cicatrices, and a recent ulcer which had perforated the wall of the bowel and allowed fecal matter to escape into the peritoneal cavity. The parts operated upon were not involved and the wounds had closed.

It should be borne in mind that the eliminative power of diseased kidneys may be very seriously diminished by an abdominal section, even so as to arrest their function and destroy a patient, who without such an exciting cause might have lived much longer, notwithstanding their diminished activity: hence where albuminuria exists the prognosis should be unfavorable: Dr. Beumer's case, the second on record, died from kidney disease in forty hours.

A very rapid pulse makes the prospect of an operation unfavorable, but has less weight now than under the old operation in determining a prognosis. We have known two women to recover whose pulses before the knife was used counted 143 and 142 beats, respectively. Long labor and exhaustion therefrom, where no futile attempts to deliver by the forceps, version or cranitomy have been made, do not necessarily render an operation hopeless, for cases have recovered in this country after labors of seven, ten and fourteen days, respectively. Experiments at forcible delivery, such as have been named, are much more likely to give an operation a fatal issue than a simple delay through ignorance.

In a hundred Cæsarean cases there will always be some that simply increase the general mortality, being in themselves positively hopeless for the mother. Where there exists, for example, a cancer of the vagina, rectum and nates, with a pulse of 168, as in the Polk case of New York, or where the urine is highly albuminous and shows tube-casts, as in the Norment case of Baltimore, the operation is in the interest of the fœtus and to diminish the agony of the mother. Such operations count one each, against the surgery, as statistics are too often estimated. Hopeless cases should occupy a middle position between those that have some hope of a favorable termination and those that are operated upon *post-mortem* to save the fœtus, and should be separately classified.

The prevalence of rickets and malacosteon must eventually determine the number of Cæsarean operations that are to be performed in a given city, district or centre. Under the old method, the chief records were made in Vienna, Paris, Milan and Naples. Paris introduced the *brise-tête*, and still, through her leading obstetricians, favors craniotomy and embryulcia, although the death-rate under infantile destruction is much higher than under the Sänger operations of Germany and Austria: she has only as yet had four of the new form of operation. Milan has not yet had a case, as her Maternity is under the direction of the originator of the Porro operation. The "Hospital for Incurables" in Naples still carries on the operation of Sigault, in which Prof. Ottavio Morisani has strong faith: he has once performed that of Sänger; but that was in July, 1886, and unfortunately the woman died of septic peritonitis in thirty hours. The uterine wound had closed, and there had been no escape of fluid into the peritoneal cavity. Although in a private letter he has expressed himself as pleased with the evident capabilities of the operation, he has not again made trial of it.

The obstetricians of the Vienna Krankenhaus, although much more tardy in their initial trial of the Sänger method, as compared with their adoption of that of Porro, have at the end of five years entered with zeal and success into the work. Dr. Ehrendorfer, of Vienna, operated upon a very unfavorable case in September, 1884, which terminated fatally; and it remained for Prof. August Breisky, in October, 1887, to make the second trial. Great credit is due him for his willingness, after having had three deaths in Prague, to make a fourth trial at Vienna of the new method, when he had had such a series of earlier successes with that of Porro. Happily he was repaid by entire success, and has the honor of having initiated in the Maternity a method of relief which appears destined to accomplish great results under her obsetrical staff, eight cases having already terminated with success in about as many months.

Cologne is another of the centres of Cæsarean necessity, where the old operation has had a mortality under one operator of sixteen cases out of twenty: we have not heard of any Sänger case there as yet. Besides the popularity shown by the 44 operations of Dresden, Leipzig and Vienna, the new Cæsarean method is in much favor in St. Petersburg, Freiburg, Hamburg, Berlin, Warsaw, Florence, Utrecht, Basle and New York. Great Britain will

be one of the last countries to give up her old prejudices. She tried laparo-elytrotomy twice; the Porro operation a few times; and she has had two Sänger cases, more or less modified, since October, 1886: the Porro method alone gave any encouragement by success.

The work of the present year shows a decided increase over that of the past, in the fact that twenty-six cases have been reported for the first six months, being nineteen European with three deaths, and seven American with three deaths. Two of the three deaths in our country were in subjects hopelessly diseased before the operation, and the third was at the time profoundly narcotised with morphia.

There have been sixteen Cæsarean operations in the United States since January 1, 1887, one-half of them in the present year, and all but one claiming to belong more or less closely to the German type. Of the *favorable* cases four recovered and one died: of the *unfavorable* cases, four recovered and five died; and of the *hopeless* cases both died: twelve of the sixteen children were saved.

As nearly as can now be ascertained, seventy-two of the first hundred Sänger cases in chronological order were saved, against forty-one of the first hundred under the Porro operation: the mortalities were therefore twenty-eight and fifty-nine per cent., respectively. The forty German and Austrian operators have performed eighty-six Sänger operations and saved seventy-one women, or a fraction over seventy-eight per cent. This leaves forty-five operations for the rest of the world, divided among thirty-three operators, saving twenty-four women, or $53\frac{1}{3}$ per cent., which is apparently not very creditable to the outside operators. As New York and Philadelphia have saved six women out of a total of eleven, under seven operators, the work in the two cities is only a fraction above this average, or $54\frac{6}{11}$ per cent. The difficulty in our country, which has had twenty Sänger operations with eleven deaths, or 55 per cent., lies mainly in the fact that the patient is too often subjected to the knife when in a condition unfavorable for recovery, as we have already shown by the record of the past eighteen months, which is our best, in which one-half of the cases were saved.

What chiefly concerns the American Gynecological Society is to determine how the improved Cæsarean operation of Germany may be made as successful here, as it has been in the country where it originated. Dr. Lusk has shown how it may be done with three cases without a death, and Dr. Kelly has followed his example with two. It is evident that it can be done, and the point to be attained is the presentation of the woman to the operator in a favorable state, which means where there has been no futile intermeddling. There was a time when every hospital Cæsarean case in the United States died, and the tenth was the first that did not: there have now been twenty cases and the recoveries have increased to seven, all being the result of the Sänger method. Much of the success in Europe has been attributed to her maternities, which were at one time regarded as pest-houses. The question between the relative value of the hospital and private house should be considered.

The yellow fever outbreak in Florida does not appear to be gaining any headway, and the indications from the present outlook are that it will not last long, unless the cases now under treatment at Jacksonville should develop new centres of dissemination, and the Jacksonville Board, of which Dr. Mitchell is President, is doing all it can to prevent this. The fumigation system now practised is the only new thing yet developed by the epidemic, that is to say, movable fumigating cars adapted for the use of sulphurous acid gas.

During the winter session of 1887–1888 over three hundred and thirty-five physicians attended the courses of instruction of the Post-Graduate Medical School of New York, an increase of more than sixty per cent. over last year. In the hospital department about four hundred operations were performed, all of major importance. This remarkable increase in the matriculation list has necessitated both larger clinical space and hospital accommodations, so that a new clinical amphitheatre has been erected and will be used for the first time at the opening of the winter session, September 17, 1888. A new and commodious laboratory has been erected and furnished with the latest apparatus for the study of normal and pathological tissues. The nose and throat clinical room has also been enlarged.

Professors Abraham Jacobi, Robert F. Weir, Joseph E. Winters, L. Bolton Bangs and Peter A. Callan have been appointed to the faculty.

Prof. Rydygier has been elected dean of the medical faculty at Cracow. The erection of the surgical clinic is in active progress, the formal laying of the corner-stone having taken place in June.

An Italian Congress for Hydrology and Climatology will be held on the 10th of October at Bologna. Prof. Muni will preside. An exposition will be held in conjunction with the Congress.

Prof. Laschkewitsch, of Charkow, recently deceased, has bequeathed 50,000 francs (about $12,500) for the erection of a laboratory for experimental physiology.

A new journal, entitled *La Médecine hypodermique, antisepsie médicale au moyen des injections sous-cutanes*, under the editorship of Dr. J. Roussel, has appeared at Paris.

The prize of the Caucasian Medical Society for this year has been awarded to Dr. Kuerharski, of St. Petersburg, for his thesis "Upon the Microörganisms of Trachoma." The paper has been published in the proceedings of the Society.

On the occasion of the Meeting of the British Medical Association at Glasgow, the University of Glasgow conferred the honorary degree of LL.D. upon a few of the distinguished members of the profession who attended the meeting. The foreign list comprised Dr. Fordyce Barker, of New York, Prof. Ball, of Paris, and Prof. Benedikt, of Vienna.

It is proposed by Sir William Bowman's friends to make public acknowledgment of his distinguished services to ophthalmology and to physiological science, in the form of a portrait of himself, together with a reprint of some of his works. A committee has been formed to carry out this project, of which Dr. George Johnson is treasurer.

The 1889 Meeting of the British Medical Association will be held at Leeds, and Mr. Wheelhouse has been selected as President-elect.

REVIEWS.

A System of Obstetrics, by American Authors. Edited by Barton Cooke Hirst, M.D., Associate Professor of Obstetrics in the University of Pennsylvania. Volume I. 8vo. pp. 808. Philadelphia: Lea Brothers & Co., 1888.

This, the companion volume to the "System of Gynecology, by American Authors," places before the profession the first half of the four volumes intended to form the series. Similar in plan and execution to its predecessor, it equals it in the excellence of the subject matter and the perfection of the publishers' art.

Of the eight articles which it contains five are distinctly practical: "The History of Obstetrics," by Dr. Engelmann, and "The Physiology of Ovulation," by Dr. Martin, are highly interesting from a scientific standpoint; while "The Mechanism of Labor," in six positions, by Dr. Penrose, is the literary embodiment of its author's professorial teachings for the last quarter of a century.

As a treatise for the use of the practitioner the volume will be found to represent admirably the obstetric science of the day, as exemplified in American practice.

The Ethics of Marriage. By H. S. Pomeroy, M.D., of Boston. With a Prefatory Note, by Thomas Addis Emmett, M.D., LL.D., of New York; and An Introduction, by Rev. J. T. Duryea, D.D., of Boston. 8vo. pp. 198. New York: Funk & Wagnalls, 1888.

The author states that his first intention was to write a tract, and in this he has been successful. He regards the production of healthy offspring as the chief end of marriage; and so impressed is he with the frequency of procured abortion, that he has written this tract to rouse the sentiments of his fellowmen, and to urge the enforcement of existing laws; he appends tables showing the legal statutes of the States and Territories upon this question. To encourage the timid, he urges that reproduction is a healthful, invigorating process, adapted to improve the health of those who may be frail, but without organic disease.

We have been fortunate in failing to encounter the aversion to childbearing among the well-to-do which occasions the writer such disquietude. The cultivation of outdoor sports has produced a generation of Americans quite capable of all the functions of the healthy animal, and not afraid of, or averse to reproduction. They and their children represent the mental and physical improvement of a generation, and promise better things than frequent abortions.

We know of but two statements which, in our experience, have influenced persons in this matter. First, there is no preventive of conception but complete abstinence; second, abortion is often fatal to the mother, always dangerous. Any argument or array of statistics which enforces these points is of value. But from the ethical argument we expect nothing; those who are base enough to contemplate abortion will heed no argument but that of self-interest.

We believe that the personal influence of the physician, in refusing to listen to requests to procure abortion, and his emphatic statement of facts, are his sphere of action in such matters, in which he is powerful. But from sermons by physicians and prescriptions by clergymen we hope for little good.

SOCIETY PROCEEDINGS.

CONGRESS ON TUBERCULOSIS OF MAN AND ANIMALS.

Held in Paris, July 25 to 31, 1888.

July 27th—Evening Session.

(*Specially reported for* The Medical News.)

(Continued from page 195.)

ON THE PERSISTENCE OF THE GERM OF TUBERCULOSIS IN RIVER WATER.

MM. Chantemesse and Widal, of Paris, stated that they made researches to ascertain how long the spores

of tuberculosis would live in Seine water. Some samples of water had been, some time previously, sterilized, and the cultures containing many tubercular spores were placed in them; others received the cultures directly without previous sterilization. Half the tubes of each section were kept at a temperature of 46.4° to 53.6° F.; the other half were kept at the temperature of the room, 59° to 68° F. Every eight days, water was taken from the tubes kept at a cold temperature and those at a moderate one, and were then placed in Pasteur's vials containing glycerized broth, according to Nocard and Roux's method. Pasteur's vials were then placed in the heating stove. At the end of twenty days and one month, one cubic centimeter of each of the tubes which, without previous sterilization, had received germs of tuberculosis was inoculated into the peritoneum of guinea-pigs. The results were as follows: The germ of tuberculosis was preserved for fifty days in sterilized Seine or river water kept between 46.4° and 53.6° F. It was preserved for seventy days in river water, previously sterilized, and kept at a temperature of from 59° to 68° F.

Besides the question of the vitality of the tubercular germs, is the no less important problem of their virulence. The guinea-pigs inoculated with one cubic centimeter of water, which contained for fifteen days germs of tuberculosis, were sacrificed after two and a half months. Not one presented any trace of tuberculosis. This result was due to the feeble dose of inoculated germs, or to the attenuation of these germs in a more or less cold water, or to both of these causes.

M. Arloing, of Lyons, in connection with the facts presented by MM. Chantemesse and Widal, desired to call attention to experiments made by MM. Galtier and Cadéac, in regard to the resistance of the bacilli in contact with river water. These experiments had been made under two conditions. Tubercular fragments were placed in running water; fifteen days later the fragments were very virulent. In running water the virulence was maintained for one and a half months; in stagnant water, an inoculation made on the 120th day gave positive results, while one made on the 123d day was negative.

General or Local Means Capable of Arresting the Extension of Experimental Tuberculosis.

M. Arloing has tried to prevent the extension of tuberculosis, as some have tried to prevent the spread of syphilis, by extirpation of the chancre and neighboring lymphatic gland. In the guinea-pig, the best place for inoculation is the mammary gland, which also contains the nearest lympathic gland. He inoculated several of these animals, and on some of them, on the seventh and fifteenth day, he performed the total extirpation of the initial lesion and neighboring gland; and then killed all the guinea-pigs on the same day. He found them all tuberculized to the same degree, whether the gland and point of inoculation had or had not been excised. In another set of experiments he excised on the ninth day, before there were any inflammatory signs of the success of the inoculation, but, notwithstanding that, all the animals became sterilized.

It had been hoped to attenuate the severity of tuberculosis by inoculation of a virus which was attenuated by passing through an animal, but inoculation of this attenuated tuberculosis does not prevent the evolution of true tuberculosis.

Scrofulosis, which has been considered as an attenuated tuberculosis, can be inoculated; but a true tubercular virus will also take on the same subject and produce all the lesions of tuberculosis. Hence we cannot rely on an attenuated tuberculous virus, which would be rendered so by passing through the organism of an ox.

Like M. de Brun, in regard to malaria, he endeavored to ascertain whether certain antagonistic microörganisms would not prevent the growth or development of the tubercle bacilli. As the microbe of typhoid fever had been cited as an opponent of Koch's bacillus, he saturated guinea-pigs with the typhoid virus: tuberculosis developed perfectly on them nevertheless. He still hopes that a vaccine of tuberculosis will be found; and he mentioned the fact that MM. Raymond and Arthaud have rendered animals less apt to contract tuberculosis by a tannic impregnation.

Bacterial Associations of Tubercle Bacillus.

M. Babès, of Bucharest, said that out of 73 post-mortems of children, he found 65 cases of tuberculosis of the glands. Koch's bacillus was found 45 times. Out of 52 post-mortems of extensive tuberculosis, Koch's bacillus was only found alone 10 times. In 42 out of the 52, tuberculosis was very apparent; but in all those cases Koch's bacillus was associated with other microorganisms. The bacteria that complicate tuberculosis in children are the streptococcus aureus and albus and the pus streptococcus.

In tuberculous peneumonia, pleurisy, peritonitis, or meningitis, Koch's bacillus is always found associated with other microbes; and these additional microbes are those that are found and produce the disease of the organs invoved—Friedländer's microbe for pneumonia, etc.

In local tuberculosis of bones and articulations we have a complication by the addition of the pus streptococcus, which is found in all organisms. Tubercular lesions are the doorway by which these different microbes invade the organism, and mix with the tubercle bacillus. In children especially, tuberculosis rarely kills without additional complications; one must also admit that latent encapsulated tuberculosis, very common in children under the form of tuberculosis of the lymphatic glands, can become very active and severe under the influence of other microbes.

Ganglionic Caseo-tuberculosis.

M. Duret, of Lille, described three forms of tuberculosis of the lymphatic glands, which are each to be treated in a different manner: 1st, a fibro-caseous form; 2d, a caseous-tuberculous form; 3d, an ulcerative or fistulous form. For the fibro-caseous form, he recommends simple incision with the knife and extirpation of the glands. In simple caseo-tuberculosis, we must distinguish those forms in which the tuberculosed lymphatic glands are separated in chains, and those that form one single, compact and agglomerated mass.

In the first case, each gland should be treated by igni-puncture; in the second case, the entire mass must be incised with the red-hot iron, in the form of a cross. In the fistulous form, these must be opened with the thermocautery and the suppurating cavities thoroughly cauterized.

ON PSEUDO-TUBERCULOSIS OF MAN AND ANIMALS.

MM. Cornil and Toupet, of Paris, said that at the beginning of this year Dr. Routzer gave them for examination a tumor, the size of a pea, which had been extirpated from a finger. On microscopical examination, it was found to be composed of fibrous tissue, in the middle of which were a number of round embryonal nodules, looking like tubercular follicles; they also found amidst these characteristic giant-cells. Bacilli, however, could not be found. These nodules were quite limited at their periphery, and no extension of embryonal cells from them could be seen; finally, in the centre of the follicles, they could not find any degenerated cells, as are found in a typical tubercle. This little tumor had for its origin a small wound produced by an oyster-shell; the wound healed rapidly, but an indurated nodule remained beneath the skin. Having learned the origin of the trouble, they examined their specimens again, and found little fragments of oyster-shell; they diagnosed pseudo-tuberculosis produced by the penetration of small foreign bodies under the skin.

M. Cornil mentioned an analogous case, observed in an antelope, which had apparently tuberculous nodules, but no bacilli could be found, except an ovoidal bacteria, which was probably the cause of the affection; but here was an anatomical lesion, identical with the one produced in the tissues by Koch's bacillus; this is a new example of pseudo-tuberculosis. Can the difference between true and pseudo-tuberculosis always be made? In the oyster-shell pseudo-tuberculosis they could find no degenerated cells in the centre; while in the antelope, on the contrary, the degenerated part was very large and contained filaments of fibrin which are not found in true tuberculosis.

RAW MEAT AND BLOOD AS FOOD FOR TUBERCULAR PATIENTS.

M. Hureau de Villeneuve, of Paris, considered not only the use of raw meat a dangerous proceeding, on account of the microörganisms which might be taken with it, but also he did not think it of great use as a food. Raw meat is not always palatable, and with phthisical patients we must be particularly careful not to produce a disgust for food. To his phthisical patients he gives excitants, like strychnia and arsenious acid, which increase the appetite remarkably; as to food, he gives the patient what he likes.

ON SURGICAL INTERVENTION IN TUBERCULOUS OSTEO-ARTHRITIS OF THE FOOT OF A CHILD.

M. Redard, of Paris, thinks that even severe forms of tuberculosis of the ankle-joint in children can be cured by free opening of the articulation, followed by thorough scraping and cauterization with the thermo-cautery; the tuberculosed articulation must be thoroughly disinfected before and after the operation; cauterization with the red-hot iron of every tuberculous fistula or abscess; careful drainage, antiseptic bath, immobilization in plaster-of-Paris; the final result, if all precautions are taken, is a very satisfactory one.

M. Verneuil said that he had always recommended the preservation of tuberculosed articulations in children, and, above all, thorough disinfection before the knife is used; antiseptic precautions and immobility will do the rest; let us not excise a joint too rapidly, for we are able, in many cases, to preserve an articulation to our patients by acting otherwise.

July 28th—Morning Session.

Second Question: Human Races, Animal Species and Organic Mediums studied in regard to their aptitude to Tuberculosis in Asia Minor.

TUBERCULAR CIRRHOSIS.

M. Hanot, of Paris, is certain of a definite cirrhosis, having all the anatomical and clinical characters of ordinary cirrhosis, and yet due to tuberculosis. In tubercular cirrhosis one must not be astonished to find that the lesions of the intra-hepatic connective tissue are very slightly marked, for as soon as the liver is involved the tuberculosis of the lung takes a very rapid course. Even in alcoholic atrophic cirrhosis, we find a very limited development of the sclerotic tissue; and in certain acute forms of alcoholic cirrhosis, the new formation of connective tissue is almost entirely absent. As he should occupy himself exclusively with the lesions of the connective tissue of the liver of tubercular patients, he should not study the cellular lesions which are always present.

We are certain to-day of the mode by which tubercle bacilli reach the portal system. Intestinal lesions are not at all necessary to infect the liver, as demonstrated by Weigert, but the portal vein and lymphatics are quite able to absorb the bacilli without any intestinal lesions. How easy their absorption must be, then, when such local lesions exist in the intestine. When tubercles are found in great quantity in the substance of the liver, their etiology is easily explained; but when only very few are found, and do not occupy the neighborhood of the portal system, the action of bacilli is not so easily explained. We must then admit, like Chaon, that intestinal lesions are produced in tuberculosis, without the presence of the bacillus, as it takes place for syphilis where gummatous tumors are not so often present. He thinks, also, that the action of the soluble products derived from the microbes, can explain why this bacillus acts at a distance and not only locally. Tubercular cirrhosis has also its clinical characters; it has a typical ascites, an increase of the superficial abdominal veins, a diminution in the size of the liver. He has often thought, with M. Lauth, that the ascitic form of tubercular peritonitis could be explained by the presence of a tubercular cirrhosis, and that tubercular peritonitis is often nothing else but a tubercular cirrhosis, as is discovered at the autopsy.

ON THE FAMILIES OF TUBERCULOUS PATIENTS.

M. Ricochon, of Champdeniers, has been able to collect the personal and hereditary antecedents of 53 patients. He has found in the parentage or collateral relations, tuberculosis 181 times; 83 different neuroses—epilepsy, eclampsia, chorea, infantile convulsions, etc. In 38 patients there was congenital dislocation of the hip-joint, 33 bony deviations, next came pharyngeal and laryngeal diphtheria, cancers, herniæ, nævi, etc. The osseous deviations, congenital dislocations of the hip, herniæ, varicosed veins, seem to indicate a weakness in the fibrous and osseous tissues. This is due to a hypermineralization of the tissues, a lack of the mineral substance, which, rendering the tissues less resistant, become a favorable field for the development of tuberculosis.

HEREDITY AND CONTAGION OF TUBERCULOSIS.

M. FERRAND, of Paris, gave the observations of three families, showing an undeniable hereditary influence, in which contagion can only be secondary. One of them is composed of the father, mother and seven children; father died of phthisis at the age of seventy-five; the mother, eighty years, is perfectly well. All the children, however, have died of tubercular manifestations, white swelling, meningitis; the daughters, having married, lost also several of their children from similar diseases. In a second family, the father was considered tuberculous at twenty, a brother of his died phthisical, the mother died of cancer of the liver; they had two daughters, one died of tuberculosis at twenty-one, the other, although having had hemoptysis, lived, had four children, one of whom died very young. In a third family, the mother alone was tubercular and lost one child phthisical.

We find here that cohabitation has not produced tuberculosis in the living and healthy husband. Contagion of tuberculosis is not at all proven.

HEREDITY OF TUBERCULOSIS THROUGH THE PLACENTA.

M. MALVOZ, of Liege, thinks, concerning the passage of the microörganism from the mother to the fœtus, that it cannot filtrate through the placenta, but that for such transmission placentary lesions are necessary, lesions produced by the organisms themselves. When in malignant carbuncle, or chicken cholera, we find microorganisms in the fœtus of the inoculated animal, we find hemorrhagic lesions of the placenta, which is in accordance with Wyssokowitch's law—that is, that microorganisms can pass in the secreted fluids of the organism only if glandular lesions exist.

For the transmission of tuberculosis it is necessary that a small tubercle should break down, to enable the microbes to reach a fœtus. Such lesions, however, are very rare, as is general infection of the blood in tuberculosis; this condition is also rare, for the placenta is not favorable to the implantation of bacteria. When we speak of heredity of tuberculosis, we must have in view the fact that children of tubercular parents are more prone to the cultivation of the tubercle bacillus, and, in addition, are liable to infection, living with tubercular parents.

CONTAGION OF TUBERCULOSIS OF MAN TO CHICKENS.

M. CAGNY, of Senlis, presented the following interesting observation: on a farm a mother died of galloping consumption; her son, aged twenty-one, was also phthisical. He observed, also, that all the hens of the farm became thin, and when examined their livers were found filled with tubercles; the young man told him afterward that he was in the habit of spitting on the ground to see the hens run and pick it up. All the animals being then sacrificed and the poultry-yard well disinfected, no more tuberculosis was observed.

TUBERCULOSIS AND ARTHRITISM.

M. JONESCO, of Paris, stated that at the recent Congress of Surgery M. Peyrot and himself called attention to a tubercular paronychia on a rhumatoid nodosity. M. Verneuil remarked the rarity of the combination of the two diseases. He presented to-day another observation: a man, aged thirty, father tuberculous and mother rheumatic. Patient has had from his youth a number of attacks of articular rheumatism, the last ones having localized themselves in the lower extremities. He then married, had four children; three of them died of different tubercular manifestations; he is finally taken with hemoptysis and a fungous arthritis of the right knee. When he examined him, he had ankylosis of the right knee, and presented signs of tubercular arthritis of the left knee, and a tuberculization of the right upper lung. This rheumatism has probably created in his articulations a "locus minoris resistentiæ" for the penetration of the tubercle bacilli; it is in that manner that we can explain the combination of these two diseases.

M. VERNEUIL said that arthritism and tuberculosis are rarely associated, but we can find a sort of morbid hybrid state between the two diseases; this combination can usually be explained by heredity, the father suffering from one affection, the mother having the other. The same with anthrax; it is very rare to find it on scrofulous patients, and when they are associated it is usually found that one of the parents is arthritic, while the other is tuberculous.

MICRO-POLYADENOPATHY OF CHILDREN.

M. LEGROUX, of Paris, said that we all know of these small enlargements of the lympathic glands, which are commonly found in the neck of children, especially those living in places where hygienic conditions are wanting. To this lesion he had given the name of infantile micro-polyadenopathy. The inflamed glands are particularly situated at the neck and can be attributed to dentition, or the lympathic state. They are movable and painless; they are also found in the axilla, inguinal region, etc.; they may disappear with the advance of age, but are also frequently followed by variable accidents. They are found in children presenting tuberculous manifestations. If such children die of measles, for instance, we often find caseous tracheo-bronchial glands, or latent tubercular pleurisy, or peritonitis. If meningitis appears and this polyadenitis exists, we are able to affirm a tubercular meningitis.

M. DAREMBERG, of Cannes, had seen, on several occasions, this specific polyadenopathy in relation with tubercular tonsils; this tubercular tonsillitis is easily produced by the cohabitation of the children of tubercular patients.

NATURE OF THE ATYPICAL VARIETIES OF LUPUS VULGARIS.

M. LELOIR, of Lille, said that the classical lupus is nothing else but a tuberculosis of the skin; but other varieties of this disease he had observed for several years, which were different in a clinical, as well as in an anatomico-pathological point of view.

Tubercular lupus has a vitreous, semi-opaque appearance, with, occasionally, small cysts having undergone colloid degeneration, and leaving small cavities. Section of these nodules shows cysts colored ochre-yellow by picro-carmine, with a vitreous appearance, and the characters of colloid degeneration; these cysts are the central part of the lupus nodules; they are surrounded by a mass of embryonal cells; this central portion sometimes contains giant-cells, and occasionally tubercular bacilli can be discovered; these nodules have hardly any bloodvessels.

From numerous inoculations he concludes that this variety of lupus is only an attenuated form of tubercle;

its relation to lupus vulgaris is the same as the colloid tuberculosis of the lung described by Grancher is to the ordinary tuberculosis of the same organ; this lupus could be called lupus vulgaris—colloid variety. Another variety of lupus presents a transparent, soft, gelatinous appearance, with a great number of small bloodvessels easily seen. On their surface we often see small cysts containing a mucous substance; these lupus tubercles lacerate easily.

In this variety the embryonic cells are irregularly distributed and not compact. The dermoid connective tissue is deeply involved, and the elastic tissue fibres have almost all disappeared. Colored with picro-carmine, the embryonal cells appear red, while the disease-germ is yellow. Some of these embryonal cells have undergone mucoid degeneration, and form little nodules, composed of four to eight cells; they agglomerate around the blood-vessels; very rarely do they form a mass of cells. In those nodules giant cells are extremely rare, and bacilli are only found in their immediate neighborhood. This tubercular lupus contains numerous dilated blood-vessels.

His experimental researches with fragments of these nodules led him to believe that this atypical lupus vulgaris is nothing else but an attenuated tuberculosis of the skin; that it is a mucoid variety of lupus.

Another variety of lupus, sclerotic lupus, is to the lupus vulgaris what fibroid tuberculosis of the lung is to tuberculosis vulgaris of the same organ.

Since 1882 he had made many inoculations. The date of the appearance of this experimental tuberculosis is later for the sclerotic lupus than for the vulgaris variety. Sclerotic lupus is, then, another variety of tuberculosis of the lung.

These three forms of lupus—colloid, mucoid and sclerotic or fibroid, are attenuated forms of the lupus vulgaris, because they contain very few bacilli.

SUPPURATIVE FORM OF TUBERCULAR LUPUS.

MM. HALLOPEAU and WICKHAM, of Paris, have observed a mixed cutaneous tuberculosis, presenting both gummata and suppurated lupus nodules.

In one case, following a horse-bite, it was difficult to differentiate it from chronic farcy; the question was decided by inoculations and cultures made by M. Nocard and themselves, giving negative results. The cause of the suppuration they attribute not to Koch's or pus microörganisms, but to the action of the substances produced by these microbes, such as leucomaines; such is the explanation they also give for the formation of the specific lesions of tuberculosis.

EVOLUTION AND THERAPEUTICS OF TUBERCULOSIS IN A HEALTHY MEDIUM.

M. CALMETTE, of St. Cyr, has studied the evolution of tuberculosis in an eminently healthy place. External manifestations of tuberculosis are rare. Frequently tubercular peritonitis and broncho-pneumonia are met with, also tuberculosis of the viscera; hence he insists on treating the intestinal canal antiseptically, and the substances he has found most efficient were the preparations of phosphorus associated with sea water. He gave daily 0.5 gramme of phosphoric oil (the phosphorated oil of the French Codex), composed as follows:

R.—White phosphorus	1 part.
Sweet almond oil	95 parts.
Officinal ether	4 "

Add the ether after cooling.

For *internal* administration the following is prepared:

R.—Phosphorated oil	10 parts.
Sweet almond oil	90 "

or he gives the phosphate of zinc, in the dose of $\frac{1}{15}$ grain, at the same time prescribing two tumblerfuls of sea water.

ON THE EVOLUTION OF EXPERIMENTAL TUBERCULOSIS IN CHILDREN.

M. ARLOING said that he found it difficult to render the rabbit tuberculous. If he inoculated ten rabbits and ten guinea-pigs, he should find certain rabbits remain unaffected, while the guinea-pigs are all diseased; the guinea-pig can, then, be considered as a true reagent for the diagnosis of a questionable tubercular lesion. If we desire to know, without killing the animal, whether the inoculation gives a positive result, we can determine by ascertaining whether the neighboring lymphatic glands are involved. He has also observed that the spleen of the guinea-pig is early involved, while in the rabbit it takes place at a very late period, tuberculosis of the lung precedes that of the spleen in rabbits. As the spleen in guinea-pigs is so rapidly involved, he asked himself whether there could not exist a derivative lymphatic current to take the virus from the lower extremity to the spleen directly, without passing through the vena cava. The inoculations from the human lung to the rabbit give only a visceral tuberculosis, without involvement of the lymphatic glands of the inoculated extremity. While bovine tuberculosis appears very severe in the rabbit, he thinks that bovine tubercular virus presents a greater virulence than that of man.

M. NOCARD confirmed absolutely and on every point the opinions expressed by M. Arloing.

M. VALUDE, after an inoculation of two months' standing in rabbits, found only a few disseminated tubercles in the liver and kidneys, but rarely in the spleen or lung.

M. LELOIR has observed this perfect inoculation of the guinea-pig with lupus, but the inoculation must be made on the peritoneum and especially on the epiploon; if introduced in the cellular tissue, we may have negative results

M. VERNEUIL also agreed on the fact, that to assure promptly and surely the diagnosis of tuberculosis, the guinea-pig is the animal to be chosen, and the abdomen must be the seat of the inoculation.

ACUTE INFECTUOUS TUBERCULOUS FEVER.

M. JEANNEL, of Toulouse, said that there are certain conditions which are mistaken for early symptoms of typhoid fever, but which are in reality the prodromic stage of a coming tuberculosis. It is a real febrile tuberculosis and the temperature chart only will differentiate it from typhoid fever. In tuberculous fever, the temperature curve ascends suddenly, to remain on the same level for some time, when it comes down to a lower level. Then, too, tuberculous fever is reduced rapidly by antipyrin in small and continuous doses, whereas this drug is of no great use in typhoid fever. M. Landouzy has

also studied and described previously this particular disease.

HEREDITY OF TUBERCULOSIS AND ITS SPREAD FROM ANIMAL TO ANIMAL.

M. Bang, of Copenhagen, claims that heredity of tuberculosis in animals is rare; he consulted 165 veterinary surgeons and only 32 asserted that they had found tuberculosis in newborn calves, and these calves were sufficiently fat not to be suspected of tuberculosis.

M. Thierry, of Auxerre, related the case of a stable where all the cows became tuberculous; it was ascertained that they all took their food from the same bucket, which probably contained the specific microbes, for its removal coincided with the disappearance of the disease.

M. Van Hersten, of Brussels, mentioned the fact that in Belgium the number of tubercular cows is very large while the number of diseased calves is very small, only 1 calf out of 650, while 1 cow in 100 is tuberculous, which proves that tuberculosis is not so often hereditary and that the disease develops in the later part of life.

CORRESPONDENCE.

SOME GLIMPSES OF BRITISH SURGERY.

To the Editor of The Medical News,

Sir: During a stay of some weeks in Great Britain I have had opportunities of visiting some of the best known surgeons and of observing their methods of work, many of which seem to me worthy of mention.

In Glasgow I had the pleasure of spending a few hours with Mr. Macewen, in the wards of the Glasgow Royal Infirmary, and was especially interested in the case, which he has reported in his paper on the Osteogenesis of Bone, of almost complete reformation of the humerus, after a crushing accident of unusual extent and severity. Most of the bone was lost at the time of the accident, and the fragments which remained were torn from their connection with the periosteum. They were reimplanted in the soft tissues and served as foci for a new formation, which has now given the lad a useful limb.

Two cases of the radical cure of hernia were in the ward, in the early stages of convalescence,—too early to permit of definite judgment as to the final result. Mr. Macewen's faith in the superiority of his method over other operative procedures in these cases remains undiminished, and he kindly spent some time in explaining to me, with the aid of models and specimens, the smaller details of his plan. An interesting specimen, taken from a patient upon whom he had performed the operation for radical cure, some years ago, and who had recently died of acute disease, showed the entire obliteration of the internal ring and the associated pouch of peritoneum, which is aimed at by Macewen's operation. The thickening caused by the sac folded upon itself and placed within the ring was still perceptible. Macewen pays comparatively little attention to the canal itself and to the external ring, believing that the permanency of result, which is the object aimed at, can only be obtained by the more or less perfect closure of the internal ring and the fortification of the adjoining parts.

There was walking about the ward an interesting case of recent trephining for cerebral abscess, depending upon otitis media and diagnosed by cerebral localization.

At the London Hospital, with Mr. Frederick Treves, I saw a case of pancreatic cyst which had been tapped and evacuated a few days previously, the contents measuring one and a half gallons. The operation was undertaken for a supposed sarcomatous tumor, and Mr. Treves remarked that, among the sixteen cases which he had been able to collect, there was not one in which the diagnosis had been made prior to operation. Two cases, however, were reported in the *Chicago Medical Journal* during the early part of the present year, in which, if I am not mistaken, such a diagnosis had been made, in one case by Dr. Fenger, in the other by Dr. Steele.

In showing a case of hydrocele, Mr. Treves alluded to the treatment by injection of iodine as extremely unsatisfactory, remarking that there were at least 30 per cent of failures, but adding that, in many cases, this was due to the employment of an insufficient quantity of the tincture. If he had said that, in nearly every case of failure, the cause was to be sought in this direction, his statement would have been more in accord with our Philadelphia experience. In many dozens of cases of this character upon which I have operated, or which I have observed in the practice of Dr. Agnew, or of my colleagues, I do not remember a half dozen failures where any attention was paid to proportioning the quantity of iodine employed to the size of the sac.

Mr. Treves treats all his compound fractures in the open air, according to the following plan: When the case is admitted to the hospital, the wound and surrounding part are cleansed, but no attempt is made to arrest the oozing of blood, which, in the great majority of these cases, is still going on. Iodoform is sprinkled in large quantities and at short intervals over the wound and adjoining parts, and this is continued sometimes for two or three days. At the end of that time a scab has formed, beneath which, Mr. Treves claims, cicatrization and repair take place in the most perfect aseptic manner. The infiltration of the muscles and connective tissue, which sometimes follows the sealing of the wound in compound fracture, while oozing is still going on, is thus avoided, and with the least possible disturbance of the parts. During the entire course of the case, the affected limb, with the necessary fixation apparatus, is kept uncovered, Mr. Treves believing that the atmosphere which surrounds such a part beneath the bed-clothes is much more likely to be septic than the general atmosphere of the ward. His results in a number of cases certainly seem to justify his confidence in this method, an elevation of temperature of even a degree being almost unknown.

I saw some excellent results in cases of extensive lacerated wounds and crushes involving joints, obtained by the unusually free use of irrigation. Instead of the usual drip, a stream of water of considerable size, almost as large as a little finger, is kept running over or through the injured part for long periods, with the result, in at least three cases which I saw, of preserving limbs and joints which would have ordinarily undergone amputation or excision. The irrigating apparatus, so far as the supply is concerned, is directly connected with the general plumbing of the hospital, and arrangements for carrying off the waste are just being made. I have long

been familiar with the excellent results obtained in similar cases by our own method, but would now feel inclined to try Mr. Treves's plan in cases of greater severity.

I saw many other interesting cases, among them one of hysterectomy, for a fibroid weighing twenty-two and a half pounds, accompanied with the removal of both ovaries and appendages, but have not time to describe them.

At the Children's Hospital, Great Ormonde Street, built on the site of a house formerly occupied by Lord Macaulay, I was greatly interested in the wards and the work of Mr. Edmund Owen. In a double osteotomy for outcurving tibiæ the operation was performed by the open method, the bones being divided with a saw. As Mr. Owen remarked, operations with the chisel in this region are apt to be practically open ones, even although the attempt is made to render them subcutaneous, and the use of the saw makes the whole operation so much easier and more rapid in execution. An excision of the shoulder-joint for caries was performed by him in a masterly manner, removal of the head of the bone occupying less than five minutes from the time of the first incision through the soft parts, and the whole operation, including the dressing, being completed inside of twenty minutes. A number of interesting cases of tenotomy, osteotomy and excision were convalescent in the pretty little ward which, although it was built twenty-five years ago, has hard wood floors and glazed brick walls and most admirable provision for light and ventilation.

The great prevalence of rickets in this country, as compared with our own, is quite apparent in the service of this, as of all the other London hospitals, nor does it seem to be confined to the large cities. Professor Humphrey, at Cambridge, called my attention to the number of cases of this sort which he treated in his outpatient service, which is derived largely from an agricultural population. He believes that the majority of such cases outgrow the deformity, as is shown by the comparatively small number of adults who are so affected. In deformities of a sufficient degree to require treatment, Mr. Owen greatly prefers operative measures to the use of apparatus, which he has found tedious and, in the main, unsatisfactory. Among his ward cases I saw one of reoperation for club-foot (the first operation having been performed by another surgeon), in which Mr. Owens had used the method recommended by Dr. Willard, of Philadelphia, and of which he spoke very highly.

A day or two ago I was present, by invitation of Sir Spencer Wells, at a private ovariotomy, which was particularly interesting as being the second one performed by him upon the same patient. The first operation, done in 1864, will be found reported in his series of cases as No. 94. The left ovary was then removed for cystic disease, the pedicle being treated by the clamp method then in vogue. The patient at that time was forty years of age. Now, at the age of sixty-four, a large multilocular cyst had formed in connection with the right ovary. The operation was done with the most careful antiseptic precautions and under the spray. A short incision was made through the scarcely discernible scar of the old operation, the pedicle of the former tumor being found attached to the abdominal wall a little to the left of the median line. One of the loculi of the cyst was tapped, reducing its size sufficiently to permit of its easy extraction. The pedicle was long and slightly twisted. It was ligatured first in two portions by transfixion, and then the whole mass was included in a second single ligature. The operation was done with extreme dexterity, as might be expected, but with apparent deliberation; it was, however, completed, including the stitching and dressing, in about fifteen minutes from the time the first incision was made. Sir Spencer was ably assisted by Mr. Meredith, one of the rising men in this line of work in London, who comes from an old and well-known Philadelphia family, although he has lived abroad almost all his life. Sir Spencer Wells shows no abatement in his outspoken opposition to the somewhat indiscriminate ovarian surgery of the present day, and believes that many hundreds of unnecessary and unjustifiable operations are now being performed,—operations which will not bear the test of time or further experience.

The anæsthetic employed during the operation was methylene, of which certainly not more than two or three drachms were used. There was no apparent period of excitement, the patient came rapidly under its influence and almost as rapidly recovered consciousness, and there were no alarming symptoms of any sort. It was administered by Dr. Day, one of the physicians to the Samaritan Hospital, who has given it in between twelve hundred and thirteen hundred cases, and without difficulty of any kind. The color of the face and the character of the respiration are his guide, no attention being paid to the pulse. I see that he has reported, in the *British Medical Journal* of July 14th, the interesting fact that twelve drachms is the largest quantity he has ever administered for an operation lasting one hour, and that Sir Spencer Wells has never occupied a longer time than this for even his worst operations, including nephrectomies, hysterectomies and all the various forms of abdominal tumors, with and without complications. This statement was afterward confirmed by Sir Spencer Wells, in a conversation with me at his office, and includes a recent case of splenectomy, which recovered without a bad symptom.

My most interesting time in London has been spent in the wards and the operating theatre of Sir Joseph Lister, and I regret that I can scarcely do more than allude to the many interesting and remarkable cases which I have there seen. The admiration which I already felt for the man who has done more to advance surgery, to make it an exact science, and to lessen the sum total of human suffering than any other individual in the history of our profession, has increased by personal acquaintance with him. Like all the other truly great men whom I have ever had the good fortune to meet, he is perfectly simple and unassuming in his manner and very approachable by any one who comes to him with a desire to learn. As a teacher, he is clear and, at the same time, comprehensive, speaking in an ordinary quiet, conversational tone, saying but little during the actual progress of an operation, but explaining in advance, with great care, the indications for it, the particular method which he intends to employ, and his reasons for its selection. As an operator, he is deliberate, but very neat and accurate in all his work with the knife, wasting no time whatever, but sacrificing nothing for the sake of brilliancy. It is scarcely necessary to say that in all his work, from the preliminary preparation to the final dressing, the most

minute and scrupulous attention is paid to antiseptic details—to the arrest of hemorrhage, to the provision for drainage, to the approximation of the wound without tension. His views as to the importance of all of these points have been fully and frequently described by himself and his followers.

As his antiseptic methods are constantly undergoing modification in his efforts to find the typically perfect antiseptic dresssing, which shall be at once cheap, soft and pliable, non-irritating, yet permanently active, it may be worth while to mention the details of his present method. The skin is cleaned with a 1 : 20 solution of carbolic acid in a 1 : 500 solution of bichloride, the carbolic acid, by its affinity for oily matters, carrying the more active mercurial solution into the recesses of the skin, the mixture being much more potent than either the carbolic or bichloride solutions separately. Next to the wound, in place of the old silk protective, is laid a piece of gauze which originally contained Sal Alembroth, the latter ingredient being, however, first washed out of it in a 1 : 20 carbolic solution; this is with the idea of protecting the edges of the wound from permanent contact with the mercurial salt, which is more or less irritating. The carbolic in the piece of gauze, soon disappearing, leaves an aseptic covering directly in contact with the edges of the wound. Over this is applied a much larger dressing, consisting of from eight to sixteen layers of gauze wrung out of a solution of bichloride (1 : 4000), and over this numerous layers (eight to twenty) of gauze containing 3 or 4 per cent., by weight, of the biniodide of mercury. This salt, which is the latest antiseptic used by Lister and with which he is now experimenting, is comparatively insoluble, requiring 6000 parts of water, by weight, to dissolve it, although it is freely soluble in 200 parts of blood serum. The latter solution retains the most active antiseptic qualities. Its permanency and insolubility render it particularly valuable by lessening the probability of its being washed out of the dressings by the discharges. It is, however, extremely irritating, and not only the wound, but also the skin and surrounding parts must be carefully protected from contact with it by the interposition of the damp bichloride gauze already spoken of. It was interesting to see that, even in dressings which had remained *in situ* for a week or more, and had been thoroughly soaked for that time in the wound discharges, the portion of gauze from which the red color of the biniodide had been thus washed out would still promptly give the characteristic reaction with sulphide of ammonium, indicating the presence of the salt in sufficient quantity to preserve the antiseptic property of the dressing. Over this, without the interposition of any layer of mackintosh, is placed the antiseptic bandage or cloth, made of the same gauze, soaked and dried in a 1 : 4000 bichloride solution, which serves to retain the dressings in place.

Sir Joseph is not yet prepared to publish the details of this method, and, with characteristic caution, is waiting until he has employed it in a sufficient number of cases to discover all its possible defects, and to test thoroughly and completely its full antiseptic value. I was greatly interested in observing his attention to even the smallest details connected with this method. As he went through the ward, dressing all the important cases himself, each portion of the gauze, as it was removed, was carefully inspected by him, the discolored or bleached areas tested with sulphide of ammonium, and any unusual stain or hue carefully noted. On each occasion that I have been with him he has spent from two to four hours in his wards, but the results there obtained amply justify the time and care which he bestows upon his patients.

In an excision of the breast for carcinoma, the patient being a large, fleshy woman, and the tumor of unusual size, I saw the whole of the large operating wound, including that made in cleaning out the axilla, united throughout almost its entire length by first intention at the end of six days. I noted that, in dressing this case, no effort was made to make pressure upon the flap, and that the arm of the affected side was included in the dressings, the bulk of which were placed behind it, near the posterior aperture, for drainage. A broad band loosely applied, and a large piece of antiseptic gauze, also applied very loosely, completed the dressing, which at no time gave the patient the slightest pain or inconvenience. I have been accustomed, in dressing these cases, to apply the antiseptic roller with considerable firmness, with the idea of arresting any possible consecutive oozing and of promoting a rapid union of the flaps to the subjacent parts; but I shall certainly feel inclined in the future to apply looser dressings. Sir Joseph says, "When the patient is uncomfortable, you may be sure there is something wrong with the dressing."

There were in the wards two cases of ununited fracture of the patella, recently operated upon. In one case (a very large, powerful man), in which the lower fragment had been extremely small, Sir Joseph made passive motion for the first time at the end of the sixteenth day, explaining that he would have done so earlier if it had not been for the disproportion between the two fragments rendering the hold of the wire upon the lower one more insecure than usual. In the other case, which was of considerable standing before the operation, he had been unable to secure approximation of the fragments without incision of the quadriceps, which was much shortened. He elongated it by the method devised by his former pupil, Dr. Cameron, of Glasgow, which consists in first freeing the under surface of the muscle from the bone by means of a blunt instrument introduced beneath the upper fragment of the patella, and then incising obliquely the muscle itself at two places, the cuts beginning at the inner and outer edges, a short distance above the patella, and running parallel with each other nearly to the opposite edge, and extending through the entire thickness of the muscle. This permits of great elongation, without completely dissevering the continuity of the quadriceps. In this case, six days after the operation, on account of the restlessness and intractability of the patient, muscular spasm occurred, followed by extensive oozing from these cut surfaces. A large clot formed, producing considerable tension, necessitating the removal of the stitches, and causing at two points a slight separation of the edges of the wound. I watched this for ten days, and instead of the flush, the suppuration, the elevation of temperature and the alarming symptoms which would usually follow such a hemorrhage into and about a great joint, the patient and the limb both remained perfectly passive, with absolutely no sign of either local or constitutional irritation, while the clot itself gradually contracted and the knee resumed its normal outline. During all this time there was literally not one drop of pus and not a trace of offensive odor.

A severer test of Professor Lister's antiseptic methods could hardly be devised or imagined.

One of the most striking cases which I saw was an operation for the relief of the deformity caused by badly treated Pott's fracture. The fibula had been broken at the usual point, and there had also been a fracture through the base of the internal malleolus; the foot was so greatly everted that the limb was absolutely useless to the patient; this condition had persisted for more than a year. At the operation, the soft parts were turned forward down to the bone by an incision following the posterior border of the fibula and of the external malleolus; the fibula was divided at the point of fracture, the triangular space existing between the lower edge of the tibia and fibula, which was filled up with fibrous material of almost bony hardness, was cleared with the gouge, chisel and sharp spoon; the soft parts over the internal malleolus were then turned forward by a similar incision, and the mass of new bone, which was easily recognized, and which filled up the gap between the two fragments of the malleolus, was chiselled away. After this, the application of considerable force by means of pulleys brought the foot suddenly, but perfectly, into position. The subsequent course of the case was absolutely uncomplicated, and the patient, at the end of three weeks, already had considerable motion without pain in the ankle joint.

In another patient, an anterior luxation of the radius of one year's standing, rendering the elbow joint almost useless, was cut down upon and reduced. An excision of the elbow for strumous disease; an excision of the knee for gelatinous arthritis, with most extensive caries of the bones; a case of angular deformity of the femur, with great shortening, were all operated upon successfully. That is to say, at the end of from two to three weeks the limbs were in perfect position, the patients were entirely comfortable, and there had been neither suppuration, hemorrhage nor fever.

In a case of strumous abscess, and in another of empyema, Lister employed the injection of iodoform and glycerin (1 : 10) recommended by Billroth, and in another case of psoas abscess, containing twenty-five ounces of pus, he used the largest amount of the iodoform emulsion which he has ever employed—three ounces. In the case of the abscesses, the cavities were first washed out with a 1 : 100 carbolic solution, after which the iodoform was injected and retained, antiseptic gauze being fastened by collodion over the trocar puncture. The empyema occupied the entire right chest of a feeble infant, who had been previously aspirated; the pus was thick and curdy, and would not run through the trocar until a watery solution of bichloride (1 : 4000) had been forcibly injected; after that a large quantity was evacuated. The opening through the skin was made with a knife, and was rendered valvular by first displacing the skin from over the site of intended tapping. A half ounce of the iodoform mixture was used, the canula was surrounded with wet gauze during its withdrawal, the puncture was closed with sal alembroth gauze held down by collodion. The child was inverted and rolled from side to side for the purpose of diffusing the iodoform thoroughly through the abscess cavity.

In a case of extremely large ranula, which had been operated upon outside of the hospital by laying open the sac, the latter was carefully and completely dissected out by Lister, and proved to be dermoid in its origin. He remarked that in such cases, in which full antiseptic treatment is impossible, the wound being exposed to contact with the septic saliva, chloride of zinc (forty grains to the ounce) and iodoform are of the greatest advantage in preventing putrefaction for the first two or three days, a most important period, both because the freshly wounded tissues are then most susceptible to putrefactive irritation, and because they are at that time most actively absorbent.

I saw many other cases with Sir Joseph, but for want of time must reserve them for another letter. In his personal and home life he is as attractive as in his hospital wards. Among the many interesting anecdotes which I had the pleasure of hearing at his dinner table were two about his father-in-law, the great surgeon, Mr. Syme, which seem worthy of being recorded in a letter upon surgical topics. At the time Sir Joseph was making his earliest experiments in relation to the germ theory of putrefaction, he asked Mr. Syme, then in his sixty-fifth year, to observe the result of one of them, the now well-known method of preventing decomposition of animal fluids by the simple plan of allowing the atmosphere to gain access to them (after they have been boiled) through a glass tube which has been drawn out in curves. Of course, we all understand now that the preservation of the fluid under these circumstances depends upon the deposit, in the lower portion of these curves, of the atmospheric dust and germs as the air enters. Mr. Syme took in the whole importance of the great natural law thus illustrated at a glance, and said that, although he would be deeply interested in further experiments, he needed nothing more to convince him. I told Sir Joseph that we had an equally conspicuous example, in America, of willingness to learn and practise new methods after the age of sixty, and he knew at once to whom I referred, and cordially agreed with me.

The other anecdote to which I referred was elicited by my remark that the advances of surgery in the past twenty years made many of the younger men of the present day feel as though there were but little left for them to do. Sir Joseph told me that in his very earliest days in Edinburgh, when he was still uncertain whether to remain there or to begin his work elsewhere, he consulted Mr. Syme. The latter told him that he would probably do well to stay there, but remarked, in almost the same words I have used above, that it really seemed as though there were not much left to do in the way of advancing surgical science, little thinking at the time that the young man he was talking to, his future son-in-law, would almost alone and unaided effect the greatest revolution in surgery, and bring about the greatest step in advance, which has been made since Harvey discovered the circulation of the blood. Lady Lister, as might be expected, takes an interest in all surgical topics, and especially in those connected with antiseptic work, which is only second to that of Sir Joseph himself.

The kindness and courtesy with which all the London surgeons treat their professional brethren from America is already well known, but I desire to add my testimony to the same effect, and to record the gratification with which I found that men like Lister and Wells (to say nothing of their younger, but almost equally busy confrères) were willing to give up so much of their valuable time to strangers, whose only claim upon them lies in

their desire to learn whatever may benefit the sick or injured under their care. J. WILLIAM WHITE.

The Question of Relationship between Lichen Ruber (Hebra) and Lichen Planus (Wilson), by A. R. Robinson, M.D.

Multiple Pigmentary Sarcoma, by E. B. Bronson, M.D.

Dermatitis Plantaris and Palmaris, by L. Duncan Bulkley, M.D.

Raynaud's Disease and Symmetrical Gangrene in late Syphilis, by R. W. Taylor, M.D.

The Relations of Framboesia to Syphilis and Tuberculosis of the Skin, with Report of a Case, by P. A. Morrow, M.D.

Kraurosis of the Vulva (Breisky), by C. Heitzmann, M.D.

Molluscum Contagiosum, a Clinical Report, by H. W. Stelwagon, M.D.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 14 TO AUGUST 20, 1888.

SUTHERLAND, CHARLES, *Colonel and Medical Director*.—Directed to inspect the Medical Department of Forts Brady, Mackinac and Wayne, Michigan; Forts Porter, Niagara and Ontario, New York; Madison Barracks and Plattsburg Barracks, New York; Fort Preble, Me; Fort Warren, Mass; Fort Adams, R. I., and Fort Trumbull, Conn.—Par. 7, *S. O. 168, Division of the Atlantic*, August 16, 1888.

JANEWAY, JOHN H., *Major and Surgeon* (U. S. Army).—Granted leave of absence for one month, on surgeon's certificate of disability.—Par. 2, *Special Orders No. 41, Division of the Pacific*, August 8, 1888.

BROWN, HARVEY E., *Major and Surgeon* (U. S. Army).—Upon being relieved by Captain and Assistant Surgeon William C. Gorgas, to proceed to his proper station, Jackson Barracks, New Orleans, La, reporting in person to the commanding officer of that post for duty.—Par. 8, *S. O. 187, A. G. O.*, August 14, 1888.

TORNEY, GEORGE H, *Captain and Assistant Surgeon* (U. S. Army).—To proceed to St. Augustine, Fla., via Palatka, accompanying the U. S. Troops thereat to Huntsville, Ala, as Medical Officer, and thereafter return to his proper station (Fort Monroe, Va.).—Par. 4, *S. O. 165, Division of the Atlantic*, August 13, 1888.

GORGAS, WILLIAM C., *Captain and Assistant Surgeon* (U. S. Army).—Leave of absence granted in S. O. 177, A. G. O., August 1, 1888, revoked, and ordered to proceed to Camp Monte Sano, Huntsville, Alabama, and report in person to the commanding officer there for duty, relieving Major and Surgeon Harvey E. Brown.—Par. 8, *S. O. 187, A. G. O.*, August 14, 1888.

WOOD, LEONARD, *Assistant Surgeon* (U. S. Army).—To proceed from Fort McDowell to San Carlos, Arizona Territory, and carry out the instructions of the Department Commander. Upon completion of that duty, to return to his proper station.—*S. O. 89, Department of Arizona*, August 1, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING AUGUST 18, 1888.

FEREBER, N. M., *Surgeon*.—Detached from the "Franklin," and ordered to the Marine Hospital, Norfolk, Va.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING AUGUST 13, 1888.

PURVIANCE, GEORGE, *Surgeon*.—Granted leave of absence for thirty days, August 13, 1888.

SAWTELLE, H. W., *Surgeon*.—Detailed as a member of the Board to select a site for a quarantine station at San Diego, Cal., August 6, 1888.

GOLDSBOROUGH, C. G., *Surgeon*.—Granted leave of absence for thirty days, August 10, 1888.

GUITÉRAS, JOHN, *Passed Assistant Surgeon*.—To proceed to Sanford and Jacksonville, Fla, and Way Cross and Dupont, Ga., on special duty, August 1, 6, 9 and 10, 1888.

BANKS, C. E., *Passed Assistant Surgeon*.—Granted leave of absence for four days, August 6 to 9, 1888.

PECKHAM, C. T., *Passed Assistant Surgeon*.—Granted leave of absence for thirty days, August 10, 1888.

URQUHART, F. M., *Passed Assistant Surgeon*.—To proceed to Way Cross Ga., on special duty, August 9, 1888.

GLENNAR, A. H., *Passed Assistant Surgeon*.—Detailed as a member of the Board to seelect a site for a quarantine station at Port Townsend, Washington Territory, August 6, 1888.

WASDIN, EUGENE, *Passed Assistant Surgeon*.—Detailed as a member of the Board to select a site for a quarantine station at Key West, Fla, August 6, 1888.

WILLIAMS, L. L., *Passed Assistant Surgeon*.—Granted leave of absence for fifteen days, on account of sickness, August 10, 1888.

STONER, J. B., *Assistant Surgeon*.—To proceed to Norfolk, Va., for temporary duty, August 9, 1888.

ORIGINAL LECTURES.

ALBUMINURIC RETINITIS.

One of the Course of Evening Lectures delivered at the Philadelphia Polyclinic.

BY EDWARD JACKSON, A.M., M.D.,
PROFESSOR OF DISEASES OF THE EYE.

THIS subject, besides its very general and important practical interest, is especially attractive, because it well illustrates the value of the ophthalmoscope as an instrument of diagnosis in general or constitutional diseases. The ophthalmoscopic changes that mark this affection are striking and, in the majority of cases, can scarcely be mistaken for anything else.

PATCHES OF FATTY DEGENERATION.

The most constant and characteristic appearance presented is that of white spots, caused by fatty degeneration of portions of the nerve-fibre and inner molecular layers of the retina and of masses of exudation occurring in these layers. You know that the normal retina is transparent, and that with the ophthalmoscope we see through it back to the pigment layer and the capillary layer of the choroid, which give the red color of the fundus-reflex, the only visible structures in front of these being the retinal vessels. When, however, the nerve-fibre and adjacent layers of the retina (they being the inner layers of that membrane, the layers next the vitreous and nearest the observer) become the seat of opaque exudation or undergo the change that replaces their proper tissue by emulsified fat, nothing beyond them can be seen, and the general red of the eye-ground is interrupted by a white spot. These white spots are at first usually small, discrete and most numerous in the region of the macula lutea and its immediate neighborhood. As the case progresses, they become larger and more numerous; and often in the region of the macula they run together, forming large masses, which have a somewhat stellate outline.

The location of the spots, or of the opacity causing them, may be ascertained by the partial concealment of the retinal vessels caused by them. These vessels lie for the most part in the layers involved, sometimes absolutely superficial, sometimes buried more or less deeply in their substance. When one of them passes across an area of retina thus altered, if on the surface, it will remain visible, and be all the more noticeable for its brilliant white background; but if it dips below the surface in such an area of opacity, it will at once be lost to sight. The only other condition concealing parts of the retinal vessels, and presenting an appearance at all similar, is that of persistent nerve-sheath. Here the opacity is in the same layer, and consists of a material physically very similar; but the distribution of the spots is entirely different. In this congenital anomaly they are of comparatively large area, never more than three or four in number, often but a single one, and they almost invariably begin at the margin of the optic disk and stretch off from it in the direction or directions of the distribution of the larger masses of nerve-fibres, ending in a "feathered" or not sharply defined edge; while, on the other hand, the lesions we are now considering involve small spots, are most numerous at the macula, although they may be scattered over the whole of the visible fundus, and have edges either sharply defined or clouded by retinal œdema, which gives an appearance quite different from that of the "feathered" edge.

These white spots are to be distinguished from those caused by lesions of the choroid by the entire absence of alterations in the pigment layer in the surrounding parts. If, in this affection, alterations in the distribution of pigment do occur, they lie beneath the more superficial opacity, and are entirely concealed by it.

There is, however, one condition of the fundus oculi which even the experienced observer will have difficulty in distinguishing from the scattered small white spots of commencing or mild albuminuric disease.

In this condition, which is perhaps (like albuminuric lesions) more frequent after middle life, there are very many small white spots, generally most numerous in the region of the macula or near the disk, but with a few scattered in other parts of the fundus. These spots are always small, seem to be due to choroidal change, and are of a rather yellowish-white. I am not certain whether there is any impairment of vision directly dependent on them or intimately associated with their occurrence.

They could not be mistaken for the appearances of a violent or advanced case of albuminuric disease; but it is sometimes very difficult to make sure that they are not the beginnings of such a trouble.

Curiously enough, a patient presented herself at the clinic to-day, with white spots in the fundus, the significance of which I could not, after careful ophthalmoscopic examination, certainly determine. In this case the spots are largest and most numerous some distance above and below the disk and macula, instead of in their immediate vicinity; and while some of them have the shining white color of the retinal lesion, others are more of a yellowish-white appearance, such as the choroidal spot presents. None of them is crossed by vessels large enough to be visible, and there are no hemorrhages or spots of pigment disturbance or other appearances to aid in deciding the question. We shall have to keep this woman under observation, and by further developments within the eye, or the study of other organs, will be able to arrive at a conclusion. (She was subsequently found to be suffering from albuminuria.)

The white spots of retinal degeneration are not confined entirely to albuminuric disease, but they are found in leukemic retinitis also; and in some cases of violent

neuro-retinitis connected with coarse disease of the brain; but in these other conditions the white areas are rarely, if ever, the most notable ophthalmoscopic symptoms, while in albuminuric disease they are usually the most prominent and, not rarely, the only local evidence of disease, and on finding them in any given case, the first thought would be of renal-vascular disease. When these spots once appear they rarely disappear or even diminish. There is very little tendency to regeneration of the tissue, except when the lesion occurs during the albuminuria of pregnancy.

HEMORRHAGES.

Next in importance to the white spots are the extravasations of blood into the substance of the retina. Unlike the former, these are not lasting, but in a few days, or a few weeks, any particular hemorrhage will be absorbed and will leave either no visible trace, or simply a white spot of fatty degeneration. It is not to be supposed, however, that all the white spots, or even the most of them, result from hemorrhages. The extravasations vary in size, from areas larger than the optic disk to the smallest speck visible by the direct ophthalmoscopic examination. In searching for them it would not do to rely on the inspection of the inverted image. Cases of unmistakable albuminuric retinitis are not rare that might, by the indirect method, be readily overlooked. Hemorrhages are most numerous toward the posterior pole of the eye, in somewhat the same proportion as that region is more richly supplied with bloodvessels.

The larger hemorrhages almost always lie partly in the nerve-fibre layer, in which the extravasated blood tends to make its way between the bundles of nerve-fibres, causing the appearance of striæ, alternately white and dark red, extending in the direction of the fibres. Such hemorrhages are often spoken of as "flame-shaped," and by their appearance and distribution, in connection with the white spots, they form a picture which reminds one of the common representation of an explosion, a radiating cloud in which each object is fringed with the same radiating lines, to show that it is flying off from a centre. The smaller hemorrhages often do not present any such striated appearances, being confined to the granular layers of the retina, in which are distributed the minute vessels from which they are poured out. The color of the extravasated blood is a dark crimson shortly after it has been poured out, becoming still darker as time goes on; but never entirely black, so that it would be mistaken for a deposit of pigment, or an opacity in the vitreous humor.

The hemorrhages are in no way characteristic of albuminuric retinitis, either in the fact of their occurrence or from any peculiarity of appearance or behavior. Hemorrhages, quite similar, are found in cases of severe retinitis or neuro-retinitis from other causes. Nor are they always present in albuminuric retinitis. Even when they have been present, they may have all disappeared at the time or times that the eye is examined. Their presence, or abundance, rather indicates that there is, or has recently been, an exacerbation of the inflammatory action; or that the local disease, at least, is rapidly progressive. Still, while the entire absence of hemorrhage would not exclude the presence of albuminuria and the conditions of which it is a symptom, in a case of retinal disease, the discovery of even a single patch of extravasated blood should arouse our suspicion and induce a careful search for evidence of such a basis for the local trouble.

LESIONS OF THE VESSELS.

The simple failure of the vessels properly to retain their contents, in a situation so well protected from external injury as the retina, and where they have the external support of the intraocular pressure, must be taken as evidence of serious disease of their walls. Actual rupture, with the pouring out of contents, is commonly confined to vessels too small to be recognized with the ophthalmoscope; but localized dilatation of the larger vessels occurs. True aneurism of what can, from its size and connections, be certainly identified as a retinal artery, is probably quite rare. I have seen it in but one case; but a marked varicose enlargement of the retinal veins is common. This is often so great, as compared with the calibre of the undilated vessel, and the undilated portions may be so completely buried in the swollen retina, that it is very difficult to decide whether the blood to which a certain dark red patch is due, is contained in such a dilatation, or has escaped into the retinal tissue.

An extremely interesting condition of the vessels is that in which their walls have become, to a greater or less extent, opaque and white. This condition arises in the course of various affections involving the retina, but in none more frequently than in albuminuric disease. It may be brought about by an embolism or a thrombosis, as in a case I saw in Dr. Harlan's service at the Pennsylvania Hospital, two years ago, in which every part of every vessel, except one minute twig, had become a white band; but in other cases the change is confined to a limited portion of the vessel wall, and the passage of blood through it is not perceptibly interfered with. Here is a sketch (water-color sketches of the fundus oculi, giving the various appearances of albuminuric retinitis, and those that might be mistaken for it, were used to illustrate the subject) of the fundus of the eye of a patient who was in attendance here a few months ago, in which the inferior nasal branch of the retinal artery has walls of a brilliant opaque white for some distance from the margin of the disk, while beyond, the vessel presents an absolutely normal appearance. More frequent, still, is the condition in which the perivascular sheaths of the vessels become visible as a pair of, more or less pronounced, white lines running parallel to the vessel, close to it and sometimes widening out so as partially to conceal it.

FORMS AND PROGRESS.

It is convenient to speak of two forms of albuminuric retinitis, the degenerative and the inflammatory, although these are blended in the great majority of cases, and often one and then the other predominates at different periods in the progress of the same case. In the degenerative form the white patches, however numerous, are apt to be small and separated by spaces of apparently normal fundus; and if hemorrhages are present, they are similarly distributed. When this is the character of the case, and there is no sudden involvement of any large part of the macula, the impairment of vision is quite gradual, and the patient is likely to regard it as due to some senile change, requiring, perhaps, a special adjustment of glasses for its correction. The inflammatory form may be taken from the outset, but usually it is

assumed after some of the degenerative changes have occurred. And its appearance is often connected with some especial strain on the eyes, or with an acute exacerbation of the kidney trouble. The symptoms may vary from those of rapidly progressive degeneration, with some hyperemia, to those of the most violent neuro-retinitis, indistinguishable from neuro-retinitis arising from other causes. In so far as the case approaches the latter type, it exhibits œdematous swelling of the retina most marked in the region of the macula and disk. This swelling often buries and partially obscures the retinal vessels and patches of degeneration, giving the whole fundus a hazy and often dirty appearance.

TREATMENT AND SIGNIFICANCE.

The course of the retinal affection depends largely on the course of the general disease which causes it. Degenerative cases go more or less steadily, and more or less rapidly, from bad to worse; but useful vision is mostly retained until the close of life. In so far as the retinal lesion is inflammatory, it is liable to be aggravated by anything that causes an especial determination of blood to the organ, as use of the eyes, strain of inadequate accommodation or uncorrected errors of refraction or exposure to excessively bright light; and by greater care, in these directions, improvement in the local condition may be secured. When the inflammation, especially of the nerve entrance, has been severe, it is liable to be followed by atrophy, which causes partial or almost complete blindness.

The significance of albuminuric retinitis, as an evidence of the general condition of the system, however, is quite as important as its usual influence in impairing the function of the part involved. Its appearance may be regarded as certain evidence that the degenerative changes in the walls of the bloodvessels that occur throughout the system in connection with the chronically contracted or granular kidney are far advanced; and that, except in the albuminuria of pregnancy or scarlatina, the fatal termination is not likely to be very long deferred; not that albuminuric retinitis is strictly confined to this form of kidney disease, but when it occurs in connection with the large white or the lardaceous kidney, it will be found that the vascular condition, local and general, is markedly that which is so closely connected with the slowly contracting kidney. In so far as it is possible for any one symptom to be regarded as pathognomonic, we may so regard this one of retinitis albuminurica. While albumin may sometimes be found in the urine, sometimes be absent, the white patches in the retina, once formed, remain always; and anything like the typical appearances of this affection, in the eye of a person not suffering from Bright's disease, is certainly more rare than albuminuria in perfect health. Of those who come to us with this form of retinal disease, about 60 per cent. die within the first year after its recognition; at the end of two years, 85 or 90 per cent. are dead; and scarcely one in fifty lives to the end of five years. One observer reports that of over one hundred cases of which he had followed the history, all had died within two years from the time they were first seen; but, although the retinal lesion is certainly not incident to an early stage of the morbid process, it is very often the first symptom to arouse a suspicion of the real basis of an indefinite, though often prolonged, impairment of the general health.

ALBUMINURIC RETINITIS DURING PREGNANCY.

Occurring in this connection the disease differs as to its prognosis and significance from the account that has just been given; but this difference may be seen to depend directly on the temporary nature of the cause of the albuminuria; and the great capacity for the regeneration of tissue exhibited upon the termination of pregnancy. So long as pregnancy continues, the prognosis, both as to vision and as to life, is much the same as it is in the same conditions arising independently of pregnancy; the retinal process tending, if anything, more toward the inflammatory type; with an especial liability to subsequent partial or complete loss of sight by atrophy of the optic nerve; but when the pregnancy ends, either at term or prematurely, the whole aspect of the case changes. Not only is it probable that the kidneys will resume the normal performance of their functions and the danger to life be averted, but the retinal œdema will clear up, the white patches will begin to fade away and perhaps disappear entirely; and the vision, though very greatly impaired, will improve, at first rapidly, then more slowly, and after a while will be found, perhaps, up to the full normal standard.

On account of the complete reversal of the prognosis as to vision wrought by the expulsion of the product of conception, the question has within a few years been raised and considerably discussed: Are we in this affection justified in inducing premature delivery for the prevention of what is likely to be permanent blindness? and almost every one who has written on it has answered it in the affirmative; but we must remember that most of those who suffer from albuminuric retinitis die before the local disease has time to destroy useful vision; and although as it occurs in pregnancy, the danger may be relatively somewhat greater for sight, still the relation between the prognosis as to vision and the prognosis as to life is intimate. What affects the one will affect the other; and in the great majority of cases, the necessity of resorting to extreme measures will rest on the peril to life, which must be regarded as imminent whenever severe albuminuric retinitis exists. If a case should arise in which blindness was threatened without serious risk to life, the decision as to the induction of premature labor or abortion, would probably have to be made on grounds peculiar to the individual case.

ORIGINAL ARTICLES.

FOUR SUCCESSFUL CASES OF LITHOLAPAXY IN BOYS.

BY DUDLEY P. ALLEN, M.D.,

LECTURER ON SURGERY IN THE MEDICAL DEPARTMENT OF THE WESTERN RESERVE UNIVERSITY.

FOR the successful performance of litholapaxy upon boys, and its introduction as a safe operation, we are indebted to British surgeons in India. One year ago, the operation had been rarely performed, if at all, in Europe. Instruments were difficult to get, and those manufactured by the celebrated firm of Weiss & Son, of London, had gone chiefly to India.

In January of this year (1888), lithotrites suitable for crushing vesical calculi in children were ex-

hibited in the Surgical Section of the Academy of Medicine in New York, by Dr. R. F. Weir, as a curiosity. Since then the operation cannot have become a very common one in the United States, the report of several successful cases, and remarks upon them, may be of interest. Three operations were upon boys who had not yet reached puberty.

The details of the operations are, in brief, as follows:

CASE I.—James M., æt. thirteen and a half years. Has been twice cut for stone. In March, 1884, one stone was removed. In April, 1886, two stones were removed. About one year after the second operation, began to suffer again with symptoms of stone. The suffering was so intense, at times, that the screams of the boy could be heard through the neighborhood.

Feb. 27, 1888. Performed litholapaxy, removing a phosphatic stone. The stone, being soft, was crushed with ease. Weight 80 grains. Largest diameter, as measured by lithotrite, one inch. Dr. A. J. Cook, who kindly invited me to perform the operation, and who cared for the patient subsequently, reported the next day that the temperature was 98½°. Slight local tenderness. Patient passed water without difficulty, but when desire occurred must micturate at once.

Two days after the operation, I found the patient eating a hearty supper and feeling well. Up to the present time (August, 1888), there have been no recurring symptoms of stone and the urine is normal.

CASE II.—Paul S., æt. fifteen years. Not yet reached puberty. For three years, patient has micturated frequently, and of late suffered considerable pain.

May 30. Performed litholapaxy. Stone was of uric acid and very hard. Its largest diameter, as measured by the lithotrite, was one inch. Weight 32 grains.

The specific gravity of the fragments being high, the washing was slow and laborious.

Operation was performed without any difficulty. My friend, Dr. Sihler, who sent me and cared for the case, reports that the day following the operation a few grains of fine sand were passed; that the patient suffered very slightly from the operation and that now he is perfectly well.

CASE III.—Albert S., æt. thirteen years; has suffered from pain in the region of the bladder for about five years.

Aug. 1. Performed litholapaxy. Largest diameter of stone, as measured by lithrotrite, was one and one-quarter inches. Composition urates and phosphates. Weight of stone 145 grains. A considerable stricture of the urethra was found at the pubic arch, and great difficulty was encountered in passing instruments and considerable force was required for their insertion.

Aside from this, the operation was performed without accident. One hour after the operation, the boy was begging for his dinner. At no time did he require any anodyne, and the next day felt in excellent condition. The first time he urinated a very little sand was passed.

REMARKS.—The interest in the above operations is dependent on the fact that the instruments employed were of the calibre of No. 18 French. The difficulty of the operation depends upon the fact that the fragments of stone must be evacuated through so small a tube. It will be remembered that litholapaxy was first considered practical after Otis had demonstrated that the normal male urethra would admit a tube of a size of No. 30 and No. 32 French and even larger. At this time, the operation was considered inapplicable to boys who had not reached a development sufficient to admit large instruments.

When lithotrites are reduced to the size of No. 18 French, it is evident that more time will be required to crush with them a stone of a given size than would be the case with a larger lithotrite. There is another difficulty: if a lithotrite be constructed with flat blades, as is common in most lithotrites, impaction becomes possible. Should this occur the calibre of the lithotrite would be increased so that on withdrawal the urethra might be lacerated, since it is very tender in children. On this account it has been thought necessary to construct the crushing portion of the female blade like a loop, so that the male blade may pass entirely through it, coming out flush with the heel of the lithotrite. Though this form of blade is no hinderance in crushing the first part of the stone, while the fragments are still large, it gives rise to very great delay in crushing the small fragments remaining toward the close of an operation. The reason for this is that these fragments, though too large to pass through the evacuating tube, are still small enough to be pushed through the fenestra in the female blade.

To overcome this difficulty, we have found it a great assistance to crush the fragments remaining at the close of each operation with a lithotrite having a flat, unfenestrated female blade. We have not used it long without withdrawing it, and in each case have succeeded in screwing the male blade well home, so that no difficulty has been encountered in the withdrawal of the instrument. The lithotrite with fenestrated blade which we have used for the main part of the crushing was made for us by Codman & Shurtleff, of Boston, under the skilled supervision of Dr. Arthur Cabot, the associate of Dr. Henry J. Bigelow, and does its work admirably.

The flat-bladed instrument used at the close of each operation was made for us by Weiss, of London, after a model of Sir Henry Thompson's. Weiss &

Son are now manufacturing for boys a lithotrite with a shorter shank, which is considered more convenient.

In comparing litholapaxy with lithotomy the questions which arise with reference to its advantages or disadvantages are: (1) Is it safe? and, (2) Are its results as good?

Of the safety of the operation there can, I think, be little doubt, provided it is in skilful hands. Litholapaxy undertaken by an operator who is not conversant with its details and dangers, especially if he is not skilled in the manipulations of urethral and bladder instruments, must in all cases be a dangerous operation. If a surgeon possesses the skill requisite for the performance of the operation in adults, there is no reason why he should not succeed in children. To be sure, the instruments are small and the mucous membrane tender.

In the three operations just recorded, the water was scarcely more than tinged with blood. If there be danger in boys from the tenderness of the mucous membrane, this is more than counterbalanced by the fact that the kidneys are not often diseased, nor is the bladder so frequently rendered abnormal by the presence of sulci and projections. One very decided advantage over cutting is that the recovery is much more rapid, being complete, as a rule, in a few days, whereas the care of the patient amounts to nothing when compared with the foul and revolting bed of a patient on whom lithotomy has been performed, with the persistent eczema which often results from a long-continued discharge.

Whether the cure is as permanent as that resulting from lithotomy cannot be so positively answered. In one of our cases, lithotomy had been twice performed before we performed litholapaxy. Now, after almost six months, the urine is perfectly normal. We certainly can have no worse success than that which followed the cutting operation. Another case has recently come under our observation of the return of a stone in a boy after lithotomy. There are many such cases.

If the operation be desirable in adults, there is greater reason why it should be successful in boys. If it must be repeated, three or four litholapaxies cause far less pain and loss of time than one lithotomy; besides, the size of the urethra is constantly increasing with increasing age, rendering subsequent operations more easy, provided they should be required. It would not seem probable that stones would be reformed more frequently in boys than in adults, since their urinary tracts are certainly less liable to be in a seriously diseased condition such as renders them liable to the formation of calculi. What the tendency to the reformation of calculi may be can only be determined, positively, by a record of many cases.

In a word, then, we consider the operation of litholapaxy in boys a safe one in skilled hands. The operation is less severe; the care of the patient is vastly less; and the recovery is much quicker than in the operation of lithotomy. We believe the cure to be as permanent.

CASE IV.—This has nothing in common with the preceding cases, but is of interest in itself.

James B., æt. nineteen, some eight months since, ran a piece of chewing-gum into his urethra. This got beyond his reach and worked its way into his bladder. A calculus formed about this as a nucleus, and on January 19, 1888, we performed on the patient litholapaxy. For this we used the instruments suited to adults. The difficulty of the operation consisted in the fact that the chewing-gum constantly impacted the blades of the lithotrite, so that it was necessary to remove it frequently. All the fragments were, however, successfully removed, weighing 180 grains. The greatest diameter, as measured by the lithotrite, was 1¼ inches.

We visited the patient the next morning and found him sitting up and about his house. He said that as soon as he became conscious, after the operation, he got up and passed his urine without difficulty and with little pain.

Through Dr. A. J. Cook, who kindly called us to operate upon the case, we learn that the patient has remained well since the operation.

SOME POINTS IN THE ETIOLOGY AND PATHOLOGY OF SUMMER COMPLAINT.[1]

BY B. K. RACHFORD, M.D.,

ASSISTANT TO CHAIR OF PRACTICE OF MEDICINE AND DEMONSTRATOR OF BACTERIOLOGY IN THE MEDICAL COLLEGE OF OHIO.

1st. THE chief, if not the only direct, causes of summer complaint are abnormal intestinal fermentations of food stuffs.[2] The fermentations of this class are always caused by organized ferments, viz., bacteria.

2d. Summer complaint is a general term used to describe not a single disease, but quite a number of diseases, of which our present knowledge does not permit of scientific etiological classification.

Subsequent investigations will probably show that there are quite a number of pathogenic[3] bacteria, each capable of producing certain definite changes in food stuffs which will bring about characteristic symptoms.

3d. Summer complaint being of bacterial origin is, necessarily, an infectious disease. The infectious nature of this disease is well established by clinical

---

[1] Read before the Cincinnati Academy of Medicine, June 26, 1888.

[2] See Dr. Christopher's paper, read before the Cincinnati Academy of Medicine, February 6, 1888, and published in THE MEDICAL NEWS of March 3d.

[3] The term pathogenic is here used to mean *a disease-producer*, it matters not whether it acts directly or indirectly, or from without or within the body. This is not the accepted use of this term in bacteriology, but it should be.

testimony, and that all diseases embraced under this term "summer complaint" are not alike infectious is also clearly pointed out by clinical observation. There is, indeed, a very great difference in this regard. In the majority of instances, this element is so obscure that clinicians frequently overlook it; but in the small minority of instances, a variety of this disease prevails, which is so infectious that the most casual observer is struck by this characteristic.

This great difference in the degree of infectiousness of various types of this disease indicates that they are altogether different diseases, each having a germ peculiar to itself, and that there is a great difference in the facility with which these germs pass from host to host, for upon this must depend the degree of infectiousness of any parasitic disease. We are not at present able to trace the parasites from host to host, and cannot, therefore, speak with certainty upon the special characteristics of the germs which determine the infectiousness of these diseases; but there are certain facts and observations which throw some light upon this question.

A. These germs escape from the body in the discharges from the alimentary canal.

B. The germs of abnormal intestinal fermentation find their way into the intestinal tract chiefly, if not exclusively, through the food and drink of the child.

C. The germs of normal intestinal fermentation[1] readily find their way into the intestinal canal in other ways than through the food and drink. This is evidenced by the fact that the intestinal tract of the young infant fed exclusively on mother's milk—a sterile fluid—is filled with bacteria.

Now, if the pathogenic bacteria could live under the same conditions as the normal intestinal bacteria, they would, like them, have a universal distribution; and if the pathogenic varieties could as readily find their way into the intestinal tract of the infant as the normal varieties can, the human race would soon become extinct, the victim of intestinal disorders.

D. The germs of normal intestinal fermentation, since they are *always* present in the intestinal tract from the first to the last moment of life, must be universally distributed and have ready access to the intestinal tract. They can probably resist the cold of winter, can live in a state of desiccation and resist other destroying agencies to which known pathogenic bacteria succumb. They are found not only in the food and drink of the child, but on everything with which the child comes in contact. Nature has provided that these bacteria, so necessary to infantile digestion, shall have no difficulty in finding their way into the intestinal canal. If it were possible to sterilize the intestinal tract, the next hour would find it filled with normal intestinal bacteria.

If, then, in our attempts to rid the intestinal canal of the infant of pathogenic bacteria, by giving antiseptic cathartics, such as calomel, we should also drive out or hinder the growth of the normal varieties, it would not interfere, to any appreciable extent, with digestion, since the calomel would soon disappear from the canal and the normal intestinal bacteria would again fill the intestinal tract. The pathogenic varieties, by reason of their feebler powers of resistance, would be much more readily destroyed and their subsequent entrance could be prevented by appropriate measures. These theoretical conclusions are, I think, amply sustained by clinical experience. For these reasons I think that Baginsky's[1] objection to the use of calomel is not a valid one.

E. The germs of abnormal intestinal fermentations probably cannot live in a state of desiccation, and must, therefore, like the typhoid bacillus, after leaving the intestine find a suitable nourishing material in which to live as a saprophyte till they accidentally find their way into the food and drink of the baby.

This accords with their limited distribution and comparative difficulty in finding an entrance into the intestinal canal, and explains why the abnormal varieties are more abundant in cities than in the country, since the conditions for the saprophytic existence of these organisms are rare in the country and everywhere present in the city. It also explains why the abnormal intestinal bacteria are not present to any appreciable extent except in warm weather, since the saprophytic existence of these organisms would be destroyed by the cold.

From these observations it follows that a cool climate, sterile food, sunlight, fresh air and cleanliness are the great prophylactic measures against this disease.

It is quite evident that sterile food has its great field of usefulness in the prevention rather than in the treatment of these diseases; for if we have an abnormal fermentation going on in the intestinal tract, producing disease, it matters not as to the continuance or activity of that fermentation, whether it be fed on sterile or non-sterile milk; either will feed the fermentation and continue the disease. I do not mean by this that sterilized milk is of no value as a food in summer complaint; it is of value in chronic cases and is indicated in all cases in which mother's milk would be indicated—that is, when milk does not aggravate the disease by feeding the fermentation which is the cause of the disease. If milk be given at all, sterile milk is much to be preferred, because of the possibility that other bacteria,

[1] The term fermentation is here used in a very broad sense to mean the changes, either directly or indirectly, produced by organized ferments by their growth or presence in any nourishing material.

[1] See Dr. Baginsky's paper published in Deutsche medicinische Wochenschrift, 1888, pp 391 and 414.

more dangerous in their fermentation products, may be introduced and a more violent disease set up as a complication of the existing disease.

With these remarks on the etiology of summer complaint, let us pass to the consideration of a question concerning its pathology, viz.: How do bacteria act in producing this disease? In a discussion which was published in THE MEDICAL NEWS of March 10, 1888, I said, in answer to this question,

"Bacteria may act in three ways in the production of summer complaint.

"1st. The disease may be caused by ptomaines."

"2d. The disease may be caused by any of the many indigestible and irritating materials formed in the process of fermentation and putrefaction."

"3d. The disease may be caused by anything that interferes with the growth and development of the bacteria so necessary to infant digestion."

I am impressed at this time more fully than ever with the truth and value of these propositions, and desire to dilate on them, that their scope and application may be more fully understood.

In the consideration of these questions we will reverse the order of these propositions.

In the first place, bacteria may cause summer complaint by interfering with the growth and function of those bacteria normally present in the intestinal tract and so necessary to infant digestion.

It is the prevailing opinion among medical men at the present time that bacteria play a very important *rôle* in the digestive process, especially in infancy. They possibly act not only by producing soluble ferments, which change starch to sugar, albumens to peptones, fats to fatty acids and glycerin, but also as organized ferments, producing the normal fermentations of food stuffs in the intestinal canal.

In all probability, the younger the child the more dependent it is on bacteria for the proper execution of the digestive function.

It is a fact of common observation that different species of bacteria growing in the same culture material exert an unfavorable influence on each other; in other words, an antagonism exists, which results in the survival of the fittest.

With these facts in mind, it is easy to understand how bacteria which do not produce poisonous alkaloids or materials specially irritating to the intestinal mucous membrane may yet cause digestive derangement by killing out the bacteria of normal intestinal fermentation, and in that manner stopping the digestive process and causing the otherwise easily digested food now to act in its undigested condition as an intestinal irritant. That food ordinarily wholesome sometimes passes through the intestinal tract of the infant and appears in the stools is not alone a matter of theory but of frequent observation.

Overfeeding and feebleness of action on the part of the digestive glands are probably too often invoked in explanation of this condition.

That this form of summer complaint is not similar to a simple intestinal irritation caused by taking indigestible food is plain to every one on reflection. In the latter, when the *indigestible* food or other materials have passed, the cause of the intestinal irritation has been removed and the child is practically well; but in the former, even after the *undigested* food has been removed, the cause of the trouble still remains—viz., the abnormal intestinal bacteria—to interfere with the digestive process and continue the disease. That the bacteria which produce summer complaint by the production of poisonous ptomaines or irritating materials may also act in this way goes without saying.

In my opinion, this cause is a factor in almost every case of summer complaint and is at times the chief, if not the sole cause of this disease. This, I think, is more likely to be the case in the milder acute as well as in some of the chronic forms of the disease.

It seems probable that this form of the disease may be a great predisposing cause to the other forms.

In the second place, bacteria may cause summer complaint by the formation of irritating materials during the fermentation of food stuffs in the intestinal canal.

This is probably the great cause of summer complaint. It is a factor in most of the cases and a chief factor in a great many.

Dr. Christopher, in his article on summer complaint previously referred to, makes two great clinical classes of this disease: "Those in which the intestinal fermentation is acid" and "those in which the intestinal fermentation is putrid."

In the large number of cases characterized by the acid fermentation, the symptoms are caused, not by poisonous alkaloids, but by irritating materials formed by an abnormal intestinal fermentation of carbohydrates.

In the still larger class of cases which are characterized by the putrid fermentation, as well as the groups of cases which have neither of these characteristics, we, in the majority of instances, do not have the slightest evidence of ptomaine poisoning; it is only in the minority of instances that this cause is active, and this is in accordance with our knowledge of the formation and physiological action of ptomaines, although the growth of microörganisms in albuminoid material probably always results in the formation of these bodies, yet it must be remembered that comparatively only a few are poisonous. The great majority of ptomaines are perfectly harmless; if this were not the case, we would have dangerous alkaloids constantly present in the intestinal tract, since the conditions necessary to their formation always exist there.

For these reasons, then, we conclude that the symptoms in those cases caused by abnormal fermentation of albuminoids are caused, in the majority of instances, not by physiological poisons, but by other irritating chemical materials formed from food stuffs during the fermentation.

In the third place, bacteria may cause summer complaint by the formation of ptomaines which act as physiological poisons.

This is the chief immediate factor in the production of the symptoms in quite a large number of cases in which an abnormal intestinal fermentation of albuminates is the cause of the disease; when this fermentation results in the formation of a poisonous ptomaine, we have the poisonous symptoms produced by the particular alkaloid formed so overshadowing all others in importance and violence that the ptomaine poisoning becomes for the time being the disease itself, to be met by prompt and appropriate treatment.

The characteristics of each case of this kind, not only as to symptoms present, but as to their violence, must depend on the quantity and poisonous properties of the particular ptomaine formed.

The three varieties of summer complaint which have been described may be spoken of in brief as, 1, bacterial indigestion; 2, abnormal intestinal fermentation; 3, ptomaine poisoning.

This classification, founded on their etiological and pathological characteristics, will, I think, be found of great value from a clinical standpoint, since the symptoms and treatment of each class must be radically different; but of this I shall have more to say at some subsequent time.

NOTES FROM A FOUR MONTHS' SURGICAL SERVICE AT THE ALBANY HOSPITAL.[1]

BY A. VANDER VEER, M.D.,

PROFESSOR OF SURGERY IN THE ALBANY MEDICAL COLLEGE; ATTENDING SURGEON TO THE ALBANY HOSPITAL, ETC.

TUMORS OF THE BREAST.

During my term of service twelve cases of new growth in the breast presented for treatment, of which seven were scirrhous carcinoma, three sarcoma, one lipoma and one cystic degeneration. In four cases there was evidence of heredity. Ten operations were done. Two cases of recurrent carcinoma were refused second operation. In four cases the axilla was invaded and glands removed.

I wish to describe somewhat fully the method which has been pursued in the operation and after-treatment of excision of the breast. After the usual laxative and general bath, the field of operation, including the axillæ, is shaved and washed with soap and water and finally with an ethereal solution of bichloride of mercury, 1 : 2000. Patient etherized, ready for operation; the instruments are brought in a tray of hot water; towels are wrung dry from a hot solution of bichloride of mercury, 1 : 1000, and spread about the field of operation and wrapped about the arm. The first incision, elliptical, sweeps around the lower border of the breast below the nipple, through healthy skin and tissue only, down to the capsule of the breast; a second incision, also elliptical, sweeps above the breast; the flaps are rapidly turned back, and the breast, capsule and muscle (if necessary) removed; the vessels are caught by pressure-forceps as divided. When the breast is removed, the wound is filled with sponges wrung from the plain hot water in which they were washed and the flaps held together by an assistant. The axilla is now opened, if necessary, to remove the enlarged glands or for exploration, either by extending the incision or by a new one and the glands turned out, together with adipose tissue. Next, the vessels and bleeding points are ligated with catgut; the wound flushed with warm bichloride of mercury, 1 : 2000; rubber drainage introduced and held in position by safety-pin properly arranged in the dressing, and the wound closed by interrupted catgut sutures. Over the line of incision a thin gauze pad moistened and sprinkled with iodoform is placed. The dressing is completed by Gamgee pads, several layers of gauze and bandage.

The first dressing is usually allowed to remain until the third or fourth day, unless considerable oozing or a rise of temperature takes place. At the first dressing the rubber drainage is removed to give place to horsehair, in fat breasts, or it is wholly left out in thin breasts when no oozing continues. The second dressing is allowed to remain a week or more. In cases in which the skin is so much infiltrated that sufficient flaps cannot be made to close the wound, the dressing is made very much the same, only boric acid ointment is substituted for dry iodoform dressing.

CASE I.—Miss H. V. S., aged forty-nine, a native of the United States, and by occupation a domestic, was admitted to the hospital October 18, 1887. Her family history showed heredity with regard to new growths; otherwise good. Previous health good. About eighteen months ago she noticed a small nodule in her left breast, to which she gave little attention. Six months later it had grown to the size of an orange and became somewhat painful. She then went under the care of a female "cancer doctor," under whose treatment she remained until a few days before admission to the hospital. Patient presented no cachexia, was well nourished, appetite has recently failed, sleepless nights due to pain. Breast very large, freely movable, somewhat nodular, and at several points a deep purple blush appeared. The day following her admission the breast was

[1] For assistance in preparing the following report I am greatly indebted to Dr. W. G. McDonald, House-Physician, Albany Hospital.

amputated; a portion of the pectoral muscle was removed. Wound left to heal by granulation. Axilla free from lymphatic enlargement. Tumor, a cystic sarcoma, weighed five pounds. Patient was discharged from the hospital November 17, 1887; wound nearly closed and healthy in appearance.

CASE II. - Mrs. M. C., aged seventy, a widow, was admitted to the hospital November 11, 1887, suffering from scirrhous carcinoma of breast. Family history revealed that her mother had died from cancer at sixty. Patient was the mother of nine children, all of whom were nursed. Always had worked very hard. Two years ago she noticed a tumor, but kept it secret from the family and her physician. Lately it had grown very rapidly and showed a tendency to ulcerate. The growth now implicated the whole breast; nipple retracted, axillary glands involved. Breast amputated, axilla entered and glands removed. Wound left to heal by granulation. Patient discharged December 12, 1887, with a healthy looking ulcer.

CASE III.—Mrs. T. R., aged forty, married, native of United States, was admitted to hospital January 10, 1888, with the following history: Mother died of cancer; a tubercular tendency upon the paternal side. Five years ago a few drops of blood oozed from nipple, and a small nodule was discovered. It grew very slowly for two years, then somewhat more rapidly until November 25, 1886, when breast and axillary glands were removed at the Albany Hospital. The wound healed kindly and patient was discharged from hospital with a clean, soft cicatrix. About three months later a small nodule appeared in the border of the cicatrix and this in turn was followed by others, spreading out over site of breast and into the axilla. January 10, 1888, patient again entered hospital. After careful examination and consultation, in view of the extent of infiltrated tissue and great probability of immediate return, I advised against another operation. I have learned that she subsequently entered a hospital in Philadelphia and was operated upon (an operation lasting about four hours), and recovered from the operation, but with a return of the growth immediately after.

The foregoing cases of tumors of the breast, which I have thought of sufficient interest to report, illustrate: First, the danger of procrastination and, also, the willingness of patients to listen to all manner of treatment that may be suggested by officious friends.

As is so often the case, these patients would have been very much better had they submitted to an early operation; and one cannot but remember the words of wisdom so earnestly expressed by the late Professor Gross, in one of his last papers, pleading for early operation in all cases of malignant growths.

The last case illustrates a point that one cannot help observing in this class of cases; that when patients have once determined upon an operation, they will have it a second, third or more times, in the hope of recovering their health, though the surgeon may not always encourage them in it. Would that they might be taught to make use of their courage early.

INTESTINAL OBSTRUCTION AND HERNIA.

Two cases of intestinal obstruction presented for treatment.

CASE IV.—Miss F. E. H., aged forty-six, single, native of the United States, and by occupation a dressmaker, gave a good family history. When fifteen years old had suffered from dysentery, followed by peritonitis, since which she has suffered much from abdominal pain and difficult defecation. For the last twelve years has been unable to secure movement of bowels except by use of large enemata. Upon physical examination a mass about the size of an orange could be made out in the left inguinal region. Uterus seemed free from growth. A diagnosis of probable solid tumor of broad ligament pressing on the descending colon made, and exploration decided upon. October 7th, a short median incision was made and the splenic flexure of colon found bound down to the left iliac fossa by old adhesive bands, a dilated portion of colon giving the appearance of tumor felt. The adhesive bands were divided and thoroughly loosened up and abdomen closed. Patient speedily recovered from operation very much improved.

CASE V.—Mr. S. V. V., aged twenty-two, single, native of the United States, and by occupation a knitter, was admitted to hospital December 1, 1887, having already suffered five days from symptoms of intestinal obstruction. His condition being very good, large enemata were given, both fluid and gaseous without success. During the following night stercoraceous vomiting again set in and an exploration was determined upon early in morning. When the abdomen was opened, a portion of the ileum was found occluded by a diverticulum having become attached to the crest of the sacrum. The diverticulum was removed, and the attached portion was invaginated upon the bowel and the opening closed by continuous catgut suture, and abdomen closed.

Patient never rallied well from operation. There were signs of great cardiac depression, and although stimulants were administered freely, he died sixty hours after operation. No vomiting occurred after operation, and bowels moved spontaneously twelve hours before death. An autopsy eight hours after death showed that the abdominal wound was healing nicely; that the peritoneal congestion had largely subsided and that the intestinal wound was closed by firm adhesion.

Three operations were done for the relief of hernia: one for strangulated femoral, one for irritable femoral and one for irritable inguinal, all successful.

CASE VI. *Strangulated femoral hernia.*—Miss N. C., aged twenty-five, single, native of United States, and by occupation a domestic, was brought to the hospital as an ambulance case, with the following history: Two days before, while lifting a tub of water, she felt a sudden giving way, with sharp abdominal pain, and noticed a small tumor in the

groin. A physician was called, who made a severe and prolonged effort at taxis. Immediately after admission the parts were scrubbed, shaved and washed with an ethereal solution of mercuric chloride; patient etherized; incision made; sac incised and a very dark and congested intestine exposed. The constriction was relieved, when the intestine improved in appearance and was returned. Sac was drawn down, invaginated, ligated with heavy catgut and removed. Wound drained by horsehair, closed with catgut, dressed with pads and bichloride gauze; over all a spica bandage of gauze. Temperature never above 99.5° F. First dressing changed on the fourth day and drainage removed; second dressing left on two weeks. Patient discharged December 24, 1887, cured, three weeks after admission.

CASE VII. *Reducible inguinal hernia.*—F. S., aged fourteen, native of United States, was admitted to hospital December 10, 1887, with a completely reducible inguinal hernia. He had been unable to have a truss fitted that would retain hernia or that could be worn with comfort. It was decided to try the Heaton method, and twenty minims of Heaton's fluid were deposited about the inguinal ring, after scrubbing, shaving and washing the overlying skin with ethereal solution of mercuric chloride. A firm pad and spica made the dressing; patient was put in bed with hips elevated, and not permitted to get up for two weeks. Considerable inflammatory reaction took place, and some induration of tissue remained when he left the hospital, December 24, 1887, cured.

CASE VIII. *Irritable femoral hernia.*—Miss M. A. D., aged twenty-six, native of United States, and by occupation a housewife, was admitted to the hospital with the following history: Last February, while lifting a heavy kettle from stove, was taken with sudden and severe pain in the lower abdomen. A physician failed to discover the hernia until six months later. The hernia, which was reducible at times, could never be retained by a truss with comfort. Late in August decided symptoms of strangulation occurred and the hernia was reduced with great difficulty. Early in October, after precautions used in other cases had been taken, sac was opened, and hernia returned, after small section of omentum had been removed by ligation with Staffordshire knot. The sac was pulled down, invaginated, ligated and removed. Dressing as in Case I. Patient recovered without material rise in temperature and was discharged cured October 29, 1887. This patient came to my office May 20, 1888, thoroughly well.

ABDOMINAL SECTION.

In the four months' service, ten abdominal sections were made, two of which were done before the class of the Albany Medical College and in the general operating amphitheatre of the hospital. Four exploratory incisions were made. In one case, extra-uterine pregnancy was suspected. The incision revealed fibroid and soft myxoma implicating the whole body of a then pregnant uterus. This operation was followed by recovery. Incisions were made in two cases of fibroid, having in view supravaginal hysterectomy or the removal of tubes and ovaries. The growths were very adherent in both cases, but the appendages were removed. One died and one recovered. Another exploration revealed colloid carcinoma arising from ovary and infiltrating mesentery. A large mass was removed, the abdomen was washed out with sterilized water (105° F.). Patient died on the fifth day from exhaustion.

Three cases of ovarian cyst were operated upon successfully, although it was necessary to sew one sac into the incision on account of adhesions. The history of two cases of intestinal obstruction have been given elsewhere in this paper. A case of hemato-salpinx was operated upon, with entire relief from symptoms.

A case of renal cyst is of sufficient interest to warrant a somewhat fuller history:

CASE IX.—Miss B. D. B., aged twenty, native of Ireland, and by occupation a domestic, was admitted to the hospital in September, 1887. Family history good. Had always been well and strong. First menstruation at fifteen, painless and scanty, but regular. First noticed enlargement of abdomen five years ago. Tumor commenced in middle of abdomen and was very hard. Two years ago grew very large and was tapped five times at frequent intervals, and a large quantity of dark, frothy liquid was drawn each time. After last tapping sac did not refill until the spring of 1887, when it began to enlarge rapidly. When first ill, suffered from amenorrhœa for a year, since which she has been regular. Since tumor appeared, has passed but little urine; and during summer had a complete suppression. Many of the facts were learned from the patient after operation; she did not give an intelligent history. October 3, 1887, the operation was done. Usual median incision was made, a large cyst (supposed ovarian) was exposed, found adherent, but tapped. The process of enucleation was very tedious and a large number of ligatures were introduced. While working for a pedicle, the right kidney was reached and the cyst's origin made out. The pelvis of the kidney, together with the vessels, was included by a single ligature, the Staffordshire knot. Patient reacted well from operation. Temperature never rose above 101° F. She rapidly convalesced and returned to her home and occupation. Have heard recently (May, 1888) that she is in good health. The average excretion of urine, for three weeks after the operation, was twenty-four ounces per day; urea approximately three hundred grains.

The fluid drawn from the cyst was dark, specific gravity 1010, contained albumin, paralbumin, abundant chlorides, no apparent amount of bile pigment, no cholesterin, and urea approximately two per cent. Microscopically nothing was determined.

While from the history of the case obtained from the patient before operation and the examination, I was led into a diagnostic error, manifestly the median abdominal incision was the only one by which the

cyst could be successfully removed. I am convinced that all growths of the kidney, cystic or otherwise, that have reached any considerable size, should be approached by the median incision. On the other hand, renal calculus, abscess, occlusion of the ureter, or any cause which may call for the exploration or removal of a not overly enlarged kidney will require the lumbar incision.

TUMORS OF THE BLADDER.

CASE X. *Papilloma with phosphatic incrustations, in a female.*—Mrs. C. K., aged forty-five, married, a native of the United States, and by occupation a housewife, was admitted to the hospital October 18, 1887. She gave a history of vesical irritability, passing sand and ammoniacal urine, containing mucus, pus and blood for the past two years. Recently has had several vesical hemorrhages. Patient etherized, urethra dilated and bladder explored by the finger. A villous growth was found upon the left side of the bladder, together with general phosphatic incrustation. The curette was used with considerable vigor and detritus removed by Bigelow's evacuator. (After-treatment will be spoken of later.) Patient discharged, improved, November 1, 1887

CASE XI. *Papilloma of bladder; perineal cystotomy (median); recovery.*—Mr. L. H., aged forty-seven, married, a native of the United States, by occupation a carpenter, gave the following history: An uncle died of cancer; family history otherwise good. When fourteen years old he received an injury to the testicle, after which it took on a neuralgic condition, and it (the left) was removed two years ago by myself. About the time of the removal of the testicle, the patient had a hemorrhage from the bladder. He was very comfortable for a year after the operation, when cystitis set in; the bladder became very irritable; hemorrhages took place at frequent intervals. He suffered from severe pain in the perineum. The prostate was enlarged and tender. Urine wholly by catheter. A careful search revealed no calculus. January 3, 1888, the patient was etherized, placed in lithotomy position, median incision made with free division of prostate. By hypogastric pressure the thickened and contracted bladder could be brought against the exploring finger. A papillomatous growth could be felt spread over a considerable area of the bladder. It was removed by means of forceps and curette. Bladder was washed with warm borated solution and drainage introduced. Patient discharged January 31, 1888, in good condition. Have received letters since, stating that he is in good health.

CASE XII. *Papilloma of bladder; perineal cystotomy; death from surgical kidney.*—Mr. F. D., aged twenty-seven, married, a native of Canada and by occupation a plumber, gives a good family history. Had gonorrhœa ten years ago; had been somewhat intemperate in his habits. Five years ago had slight hemorrhage from the bladder. Suffered more or less, at times, until a year ago, when, after great exposure, the symptoms became greatly aggravated. He entered the hospital January 4, 1888, and was treated by washing out the bladder with borated solution and the administration of various remedies, all without material improvement. February 2, 1888, the patient was etherized and the same operation done as in Case II. Patient did very well until the fifteenth day, when urinary excretion became very small, vomiting became troublesome, and the patient sank and died February 19, 1888. An autopsy showed far advanced pyonephritis. Casts had been found in the urine before operation.

The after-treatment of all the cases was very similar. Drainage was introduced in all; in Case X. a self-retaining catheter. In the other cases a large catheter was introduced through the perineal wound and retained by a rubber band attached to the catheter, the bands being attached in turn to an abdominal belt very much after the manner of a uterine supporter, the catheter cut off an inch or two from the body. This device has proved very satisfactory in our hands. Through the drainage tube the bladder was washed every day with a warm solution of benzoate of sodium (a teaspoonful to a pint). This, together with tonic doses of quinine, iron and a bland diet, constituted the whole treatment.

How long shall drainage be allowed to remain? is a vexed question here as elsewhere. In general terms, it should be allowed to remain until the urine has returned to a normal condition and vesical irritation is largely reduced or has disappeared. After two weeks a clamp may be placed over the end of the drainage tube and the patient be allowed to sit in an easy chair. There is likely to be no incontinence. The clamp may be removed from time to time and the retained urine evacuated. In this way the tolerance of the bladder may be determined.

In all these cases drainage was essential to cure. I have yet to learn of an operator who is satisfied with suprapubic drainage. The perineal route to the bladder was selected because of the superior facilities for drainage, the benefit to be gained by section of the prostate, the simplicity of the operation and the ease of after-treatment.

Case XI. was especially benefited by section of the prostate. Mr. Reginald Harrison (Lettsomian Lectures for 1888) dwells at length on the sphincter and supporting function of the prostate. In contracted bladder, long subjected to spasm and irritated by the presence of foreign bodies and chronic discharges, it seems that the division of this muscular band must be followed by the same relief that is experienced in fissure of the anus after rupture of the sphincter ani.

When the time comes for the removal of the drainage tube we shall have accomplished another purpose in many cases, the removal of the obstruction caused by the hypertrophied prostate.

The advantage of suprapubic cystotomy, by affording a view of the field of operation, is apparent rather than real. In this relation may be

mentioned three cases of vesical calculus, two of which were operated upon by litholapaxy, with one death from surgical kidney. The other case was so unpromising that no operation was advised.

SURGERY OF THE JOINTS.

CASE XIII. *Floating cartilage.*—Mr. J. R., aged nineteen, native of United States and by occupation a printer, was operated upon at the hospital January 21, 1888, and a floating cartilage the size of a quarter silver piece removed. Local anæsthesia by cocaine. The history is as follows: The fourth of July, 1887, his knee caught in a semi-flexed position while running, and he was unable to extend the leg again until he worked it a little in various directions. This accident recurred quite frequently, and finally the patient discovered a movable body within the joint cavity, which led him to seek treatment. The cartilage was caught in a pocket and retained by compress and bandage for a few days, when a clean cut was made and cartilage removed. Limb dressed on straight posterior splint, antiseptic dressing, no drainage. Patient did well, save an intercurrent attack of tonsillitis, which caused a considerable rise of temperature, leading to a removal of dressings, only to find limb in good condition.

CASE XIV. *Excision of the outer condyle of the humerus.*—Master W. C. B., aged nine, fell from a cherry tree four months prior to his entrance into the hospital, fracturing the external condyle of the humerus and dislocating the forearm backward. The treatment instituted at the time of fracture had resulted in an ankylosed joint and useless arm.

An attempt was made to break up ankylosis under ether, but it failed. An incision was made along the outer side of the joint. The external condyle removed, dislocation reduced and arm dressed on angular splint. There was a small amount of suppuration about external wound. After two weeks, passive motion was begun. The boy has gained a fairly useful arm, with free motion at elbow. Pronation and supination, as well as extension and flexion, being quite readily performed.

CASE XV. *Subspinous dislocation of the humerus. (Old.)*—Mr. R. D., aged forty-eight, by occupation a cowboy, and a resident of New Mexico, was referred by Dr. McLean, and admitted to the hospital November 30, 1888. His case is somewhat rare. I believe there are but a few more than thirty cases in the whole literature upon this subject. The accident occurred several months prior to his admission. The mechanism of the dislocation was as follows: He was herding cattle with a "bucking" mustang and was thrown over the mustang's head, striking first on his extended hand and then on the point of his shoulder. He was seen by a local physician, who claimed to have reduced the dislocation. After the dressing was removed his arm was powerless Was unable to touch opposite shoulder by four inches. After consultation an ineffectual attempt at reduction was made both by extension and counter-extension and by fixation of shoulder and manipulation. An operation for the restoration of the head of the humerus to the glenoid cavity was advised, but declined by the patient.

Amputation of the thigh was done four times, with three recoveries and one death. Three cases were of tubercular arthritis of the knee-joint. One was of thirty years' standing; had been arrested, but five years ago, while on a debauch, he fell and injured the knee-joint again, since which it has undergone continued suppuration; patient has had night-sweats and he was very feeble. Resection was impossible, owing to extensive complication of the condyles and haft of femur and of the head of the tibia.

CASE XVI.—A man, aged twenty, who gave a history of trouble with the knee dating from an injury seven years ago. The condition of the patient and of the limb was similar to that of Case XIII. Amputation was done. Both of these cases recovered. Wound healed by first intention. Sweating ceased. Both gained flesh and strength before leaving the hospital.

CASE XVII.—Miss B. H., aged sixteen, native of United States, was of the tubercular diathesis. Five years ago first began to have trouble with knee. Two years ago sinuses formed, but closed partially. Has worn an extension apparatus since. This case seemed a favorable one for excision, and all the preparations were made for the operation. The condition was carefully explained to patient and friends, and excision most earnestly recommended. Patient insisted, not without the advice of surgeons, upon a clean amputation, which was done. Patient recovered nicely, and returned to her home three weeks later. An examination of the joint showed it favorable for resection.

CASE XVIII.—A most unfortunate railroad accident. Crushing of knee and extensive laceration of soft part, with great loss of blood. Was operated upon, although patient's condition was very unfavorable. After operation patient's limbs were bandaged firmly with flannel rollers and free stimulation ordered. Later, transfusion was done, twenty ounces of saline solution being thrown into his circulation. He never recovered from the shock, and died ten hours after the operation.

MISCELLANEOUS CASES.

CASE XIX.—*Lacerated wound of hand, with fracture of metacarpal bones.*—J. H. P., aged nineteen, native of United States, and by occupation a carpenter, came to the hospital with a severe wound of the hand caused by the revolving knife of a plane. The three outer metacarpal bones of the left hand were comminuted, the extensor tendons divided and the palmar arch was wounded. Patient was etherized, vessels caught and tied with catgut. Wound was now thoroughly cleansed of foreign bodies and spiculæ of bone, 1 : 3000 solution of mercuric chloride being used for the purpose. Divided tendons were now brought together and sutured by fine silk. Drainage tube was introduced and external wound closed by catgut. Hand and forearm placed upon an anterior splint, and all dressed with iodoform and sublimated gauze. Patient had but slight febrile reaction. Wounds healed without suppuration, bones united, and after five weeks fingers could

be quite readily extended, motion being very satisfactory in all save the little finger.

CASE XX. *Vesico-vaginal fistula, with occlusion of urethra.*—Mrs. C. Y., aged twenty-eight, a widow, came to us for relief November 20, 1887, with the following history: May 7, 1887, was taken in labor with second child. Labor continued for forty-eight hours after rupture of membranes, and was terminated by forceps' delivery. After delivery, patient had severe pelvic cellulitis, terminating in abscess, followed later by peritonitis. It was soon discovered that urine flowed away through vagina. She received no treatment before coming to the hospital. Upon examination the urethra was found absolutely closed by adhesive inflammation. Great difficulty was experienced in finding the fistula, it being in a fold of the vagina high up. Anterior lip of cervix sloughed.

First operation enlarged fistula, which would only admit the point of a probe, and the opening of the urethra to admit sound by use of knife. The tract of the urethra was kept open by a self-retaining catheter and the passage of sounds. She left the hospital two weeks after operation to return for second operation. Jan. 13, 1888, she was successfully operated upon for closure of fistula. Silver wire was used for sutures. Patient now passes urine voluntarily by urethra. Advised to introduce a bougie twice a week.

CASE XXI. *Vesico-vaginal fistula.*—Mrs. M. C., aged thirty-one, married, native of the United States. Has been troubled with dribbling of urine from the vagina for seven months. She dates her trouble from birth of first child. The labor was very difficult and was finally terminated by forceps' delivery. Child weighed thirteen pounds. The edges of the fistula were freshened and wound closed with six silver wire sutures. Patient did well. Sutures removed on tenth day. Union perfect.

During my four months' service, six cases of advanced carcinoma of the cervix presented for treatment. They were all peculiarly sad ones. The patients had either not called their physicians' attention to the trouble, or it had been temporized with until all hope for relief, by radical operation, was in vain. In all cases the broad ligaments, the base of the bladder, the vagina and the rectum were either wholly or partially infiltrated by the disease. In none of the cases could amputation of the cervix, by, preferably, vaginal hysterectomy have been done with any hope of relief. The early diagnosis of this disease cannot be too earnestly insisted upon.

CASE XXII. *Perforating ulcer of foot.*—Miss I. M., aged fourteen, was operated upon at the hospital, October 29, 1887. She gave the history of having had cerebro-spinal meningitis four years ago, after which there was some contraction of the plantar fascia and Achilles tendon. Nine months ago an ulcer developed on the ball of the foot near the little toe. The ulcer was very indolent, never secreting true pus and communicated with the metatarso-phalangeal joint of the small toe. The little toe and outer metatarsal bone were removed. Wound healed very slowly, but finally united well. She was discharged September 12, 1887, cured.

CASE XXIII. *Lacerated cervix with hypertrophic elongation.*—Mrs. L. S., aged thirty-seven, married, native of the United States, family history good. Previous health good. Menstruation normal; first at twelve years. Mother of three children, oldest nine, youngest born August 15, 1887, and died soon after delivery. Five years ago, shortly after delivery of second child, patient began to suffer from pelvic pain, difficult locomotion and leucorrhœa which was untreated. During last pregnancy patient suffered a great deal, and noticed a body (the cervix) protruding from vulva. At term a great deal of trouble was experienced and instruments finally resorted to. Since delivery all old symptoms have been exaggerated. Upon exposure a body congested upon side was seen protruding from vulva. Upon introducing sound length found seven inches.

Operation.—Wire écraseur drawn moderately tight at vaginal juncture and whole body drawn down. Cervix amputated by scissors, and borders closed by silver wire. No untoward symptoms appeared after operation. Sutures removed on the ninth day. Patient returned to the hospital a month later, feeling well, uterus smaller, no discharge, no discomfort.

CASE XXIV.—This case presents one of the most remarkable histories and the greatest degree of courage that I have ever seen exhibited in any one person.

Mr. G. H. C., married and has several children; occupation, farmer; residence, Grant, N. Y.; admitted to Albany Hospital, October, 1886, and, again, on February 15, 1887. Family history free from any diathesis.

Previous history of patient.—When eighteen years old, while jumping in the snow, he struck a piece of wood bruising the perineum, but producing no wound. Twenty years later he was thrown from a wagon, striking upon his head. This accident confined him to bed for three weeks Eight years later patient began to suffer from constant pain in the back. Pain was described as constant, tearing, burning; also had a feeling of weight over bladder and in perineum. The first urine voided was frequently of a creamy consistence; later, normal. Examination of urine showed a trace of albumin, abundance of pus, but no casts. No frequent desire to urinate, no marked symptoms of cystitis or stone. Was carefully sounded several times by myself.

The first operation was done October, 1886, by making an exploration in the perineum to the left of the median line and extending back toward the neck of the bladder, midway between the rectum and tuberosity of the ischium, at a point where the patient felt certain the parts were swollen at times, and from which the pus came. I made as deep a dissection as seemed safe and proper, but failed to discover any pocket of pus. From this operation the patient made a good recovery, and later on returned to his home, feeling somewhat encouraged, but insisting upon another operation later on, and, if necessary, to open the left kidney, over which he, at times, complained of much pain.

When admitted to hospital the second time, he

was carefully examined, symptoms and condition being about the same, but was sent home, for a time, to improve in general health, before an operation.

He was readmitted to the hospital April 19, 1887, and on the 20th, in view of symptoms, together with tenderness and apparent increase of area of dulness over left kidney, an exploration was made. The kidney was cut down upon and found normal in appearance. The finest needle of the aspirator was introduced into the substance of the kidney in various directions and nothing found. Wound was flushed with mercuric chloride (1 : 2000), vessels ligated with catgut, drainage introduced, and closed with interrupted sutures of catgut. Wound healed by first intention. No serious symptoms from operation were observed. Patient left the hospital May 9, 1887, improved somewhat in mind, at least. Probable source of the pus was from an abscess about the base of the bladder.

Was again admitted to hospital October 8, 1887. His condition was the same as when last discharged, May 9, 1887. After hypodermatic injection of cocaine, patient was put in lithotomy position and median incision made upon the staff. No abscess could be found upon base of bladder within, which was carefully examined by my finger introduced.

Drainage was employed and hot dressings applied. After operation patient had three chills and a considerable rise of temperature, but made a good recovery. Left hospital November 5, 1887. Perineal wound nearly healed. Urine passed through urethra after third day.

Insists upon having one more operation, as he states he must get relief. My impression is that the abscess is situated in the vesiculæ seminales, and that an operation through the dilated rectum may reach it. November 26th he came to the hospital looking well, but there is still much pus in his urine. Passed urine six or seven times in twenty-four hours.

Case XXV. *Epithelioma of penis.*—Mr. C. M. E., aged sixty, married, native of United States, occupation farmer. Father had epithelioma. Grandfather died from some form of cancer. Eczema has been prevalent in family.

In April, 1887, was poisoned by sumach. Had previously suffered from eczema a great deal. Called a physician May 1st, when whole penis had an eczematous appearance, acquired phimosis and considerable ichorous discharge. Prepuce was slit up at that time, showing a very large ulcer. Had always been correct in his habits. Ulcer continued to increase, despite of all treatment, and became very painful. Glans at present time is twice normal size. Has the appearance of cauliflower. Patient has become broken down in health and has lost flesh. No glandular enlargement. Penis was removed near base by knife. Patient convalesced rapidly. There has so far been no return of disease.

In this case a simple elastic ligature was thrown about base of penis and controlled hemorrhage admirably.

In all, 133 operations were done. There were 7 deaths: 2 due to peritonitis, 2 to uræmia, 2 due to the exhaustion of the disease, and 1 to shock. The death-rate is, therefore, five and two-tenths per cent., not very bad, considering the class of cases that come to a general hospital for treatment.

Dressings.—Elsewhere in this paper, allusions have been frequently made to the use of antiseptics in dressings and washing of wounds. Our methods have been very simple and the antiseptic agents used neither new nor novel.

To begin with, all the gauze used is of home manufacture—that is, plain gauze medicated chiefly with bichloride of mercury. Plain absorbent gauze can be bought in two hundred yard lots at four and a half cents per yard. This is conveniently cut and folded in five yard pieces and treated as follows: First, by immersion in solution of hydrargyri bichloridum, 1 part; acid. tartaric., 15 parts; glycerin, 150 parts; aquæ ad. q. s. 1000 parts.—M. and add eosin q. s. to give a faint tint. After remaining in this solution for twelve hours, the gauze is wrung dry and packed in stoneware jars ready for use.

The addition of tartaric acid and glycerin is very advantageous, increasing both the antiseptic and absorbent power of the gauze. The bichloride gauze is used for making Gamgee pads for bandages and for iodoform gauze, by rubbing iodoform in its meshes. Iodoform and boric acid have been used in dressing ulcers, both in powder and in ointment. Boric acid solutions have been used in washing the bladder and urethra before and after operations. A one-half per cent. solution of hydrogen peroxide was very satisfactorily used about the mouth and nose. It also acts as a powerful deodorant.

For flushing wounds, 1 : 2000 or 1 : 3000 bichloride of mercury solutions were used. In my abdominal work, hot water took the place of all antiseptics, save in the dressing. The carbolic spray has been used in the room for three hours before opening the abdomen. No poisonous effects were observed during the four months from the use of any antiseptics, save in one case, in which a slight iodoform erythema appeared upon the abdomen after an abdominal section.

MEDICAL PROGRESS.

Iodides in Aortic Aneurism.—After a study of twenty-four cases, M. Germain Sée concludes that iodides are the best treatment for aortic aneurism. They have a definite action in lessening the dyspnœa, by directly acting on the catarrhal products and liquefying them. They reduce ultra-pulmonary congestion, diminish the venous stasis, and contract the walls of the tumor. They decrease the pain, and exert a beneficial influence on the aphonia and paralysis of the vocal cords, which often obtains.

He finds that patients afflicted with this disease nearly always become phthisical subjects.—*Gazette Hebdomadaire de Méd. et Chirurg*, August 17, 1888.

Congenital Narrowing of the Arterial System. — DR. FRAENKEL, on the 25th ult. before the Medical Union of Berlin, made an address on congenital narrowing of the aortic system. He remarked that hitherto it was an affection but little known clinically; what little there was known about it was pathological and principally due to the labors of Morgagni, Meckel, Virchow and others. There are great difficulties in the way of diagnosis. One of the cases was that of a powerfully built man of thirty-four, who had œdema of the lower extremities, with a pulse rate of 100 to 112, difficulty of breathing, some bronchial râles, but otherwise no affection of the lungs. Circulatory changes were the marked feature of the case. There was pronounced narrowing of the arteries, with great tension. The heart was displaced to the left and downward; the apical impulse external to the nipple line, very broad, high and resistant, as in insufficiency of the aortic valves. The cardiac sounds were everywhere pure, but the second aortic sound was strikingly accentuated. The quantity of urine was slightly diminished and it contained no albumen. The patient was of healthy family and had always been well till his fifteenth year, since when he had complained of heart trouble and occasional shortness of breath, which clearly could not have been produced by his occupation of gardener. In his twenty-first year he was a soldier, but had to be discharged, as he could not perform the marches, owing to his cardiac trouble. He returned to his occupation and became gradually worse till he entered the hospital with dropsy. With rest, digitalis and opium he improved rapidly and was discharged.

Diagnosis.—Congenital narrowing of the aortic system. Whilst at work the symptoms soon returned, and the patient again entered the hospital, where he died in a short time with great dyspnœa. The autopsy showed very marked narrowing of the aortic system, commencing at the attachment of the aorta and implicating the whole system.

A second case was that of a laborer, who entered the hospital in 1886 on account of general malaise, but without any particular complaint. All the organs were healthy, except for striking symptoms in the circulatory system. The patient, who was of extraordinary robustness, showed abnormal narrowness of the arteries, with marked dilatation of the left ventricle. The apex beat was very resistant, external to the nipple line, with accentuation of the second sound. There was absence of history of straining efforts. Although temporary improvement took place under treatment, the lungs became tuberculous and the patient died of pneumothorax. The autopsy showed striking narrowness of the whole aorta.

Such cases are most frequently met with in women and in girls, and are diagnosticated chlorosis. In men, on the other hand, who make more demands on the heart, the disease generally leads to dilatation of the left and then of the right ventricle. Cases in which such calls are not made on the heart carry the affection to their lives' ends. Rest naturally brought about temporary improvement, until the possibility of it was at an end from the advancing disease. The autopsy did not always confirm the diagnosis. He mentioned three cases, one a coachman, a second a young soldier, and a third a naval officer, in which improvement had taken place, and a restful mode of life had rendered the improvement permanent.

Résumé.—There are individuals with congenital narrowness of the arterial system in whom disturbances develop, usually very slowly, when they are subjected to exertions which are greater than the heart is equal to under the circumstances.—*Medical Press*, July 18, 1888.

Silico-fluoride of Sodium as an Antiseptic.—DR. CONRAD BERENS, in the *Therapeutic Gazette* of July 16th, after referring to culture experiments demonstrating the usefulness of the silico-fluoride of sodium as a germicide, anti-ferment and deodorant, and its property of coagulating albumen, adduces clinical evidence confirmatory of these results. The drug was used locally in solutions of from one to six parts to one thousand of water, and administered internally in doses of one grain, and proved efficacious during and subsequent to operations for cataract, in catarrhal and purulent ophthalmic conditions, in similar conditions of the nose and throat, in suppurative otitis, in uterine disorders, in gonorrhœa, in gleet, in balanitis, in gangrene, in acid fermentation of the stomach and in tinea circinata.

The silico-fluoride of sodium is soluble in water at 60° F., in proportions not exceeding half a grain to a drachm, the resulting solution being of a slightly acid taste, perfectly limpid and odorless. The writer concludes as follows: That sodium silico-fluoride is practically harmless; that it is more efficient in preventing decomposition than either bichloride of mercury or carbolic acid, in such doses as are not harmful or dangerous; that it is extremely efficient in inflammatory conditions of the mucous membranes; and that, in conditions associated with the production of pus and the results of fermentative processes, silico-fluoride of sodium acts with prompt and harmless efficiency. The more extended clinical use of the drug, I believe, will go to add further support to the evidence of its promptness and efficiency. These are reasons sufficient to call the attention of the profession to this drug.

For Chronic Acne.—

R.—Resorcin,
Pulv. amyli,
Zinci oxidi . . . . . āā ʒj.
Ung. petrolei . . . . . ʒiij.—M.

This is to be carefully applied at night, and removed in the morning by means of wadding saturated in olive oil. It causes no irritation and is very effective.—*Lyon Médicale*, August 5, 1888.

The Dietetic Treatment of Diabetes Mellitus. — CLESS (*Deutsche medizin. Wochenschr.*, 1887, Nos. 44–47) reports 56 cases of diabetes mellitus at the medical clinic at Tübingen, subjected with the best results to a purely dietetic treatment. In 4, on account of the poor general condition, a stringent diet could not be enforced; 3 were at the clinic but for a brief period; of the remaining 49, after the withdrawal of carbohydrates, sugar disappeared from the urine in 20, 2 were completely cured, and 5 almost so, in that they could take considerable amounts of carbohydrates without sugar occurring in the urine; 13 had no sugar in the urine, at least on abstinence from carbohydrates; and in the remaining 29 the amount of sugar, and in most in very decided measure, was diminished. The diet, with slight modifications, was the usual one. It is to be noted that

not every trace of carbohydrates was excluded, but the amount taken in 24 hours did not exceed 150 to 300 grains. The diet was almost exceptionally well borne; most gained in weight, and the general condition improved, sometimes notwithstanding other complications. The tentative administration of iodoform, salicylic acid and opium produced no noticeable effect.—*Centralb. für klin. Medizin*, June 30, 1888.

Sulphonal—the Influence of the Various Hypnotics upon Salivary, Gastric and Pancreatic Digestion.—CRAMER, of Freiburg before the Verslg. d. Südw.-deutsch. Neurologen u. Psychiater, stated that he had used sulphonal in four hundred and seven instances. In three hundred and seventy-seven sleep of several hours was produced; in thirty the result was incomplete, the sleep lasting only a few hours. The drug was given in tablets or with the food or drink, its tastelessness rendering the administration easy. The dose was never more than forty-five grains. Given to melancholiacs in broken doses in the course of the day the drug relieved the anxiety and restlessness, and aided the otherwise restless patients to six or eight hours of unbroken sleep. The sedative influence of the drug was marked in several instances of periodical mania.

Cramer also reported the results of comparative investigations into the influence of the various hypnotics upon the dextrin and sugar forming quality of the saliva and upon the digestive capacities of the gastric and pancreatic juices. The conversion by the saliva of the carbohydrates into sugar remains unchanged with the administration of chloral, paraldehyde, amylene hydrate and sulphonal; gastric digestion, however, is slowed by chloral, paraldehyde and amylene hydrate, while it is entirely uninfluenced by sulphonal. The function of the pancreatic juice is also almost wholly suspended by the first three, while it is undisturbed by sulphonal.

In the discussion which followed, KAST, of Freiburg, stated that the dose of sulphonal must vary for each individual case. It must especially be borne in mind that females rapidly respond to small doses. The slight solubility of the drug is increased by careful trituration and administration in a warm vehicle. Sulphonal is best given after meals.

In reply to an inquiry, Cramer stated that a tolerance to the drug did not arise and that it was not necessary to increase the dose, though the drug be taken for a long time.—*Wiener medizin. Pr.*, July 1, 1888.

Acetphenetidin.—F. MÜLLER, before the Verein für Innere Medicin, Berlin, recently stated that acetphenetidin is, chemically and actively, closely related to antifebrin. Eight to twelve grains reduce fever temperature to normal; fifteen grains are rarely necessary. The decline takes place in three or four hours and is accompanied with sweating. The apyrexia lasts three to five hours, when the temperature rises again. Chilliness is rarely noticed, rigors not at all. Tolerance is readily established, rendering increasing doses necessary. The author, in two cases, observed cyanosis, depending upon methemoglobinemia and disappearing spontaneously.

The drug exerted no influence upon the course of the disease during the progress of which it was given. It acts just as well as antipyrin, antifebrin, quinine, etc., but without secondary manifestations, such as roaring in the ears, vomiting, etc. Cyanosis may be avoided by not giving more than seventy-five grains in twenty-four hours. In the case of antifebrin, methemoglobinemia occurs more readily, because anilin is readily separated, acting as a poison to the blood.

Acetphenetidin is an anti-neuralgic in the cardiopathic headaches, in hemicrania and in neuralgias, as well as in the pains of tabes, headache, in contracted kidney, in chorea. Large doses are, however, here necessary; thirty to sixty grains must be given to obtain results. The remedy has proven itself an excellent anti-rheumatic, particularly for the early, severe symptoms, fever, pain and swelling, after which, salicylic acid readily overcomes the remaining manifestations. It ought to be useful in chronic articular rheumatism and in gonorrhœal arthritis. Like the other measures, it fails to prevent endocarditis and pericarditis. In a word, the remedy is comparable in its action to the other remedies of the group, but is preferable on account of less danger in its administration. Katz recommended the drug for whooping-cough.—*München. medizin. Wochenschr.*, July 10, 1888.

Combined Chloroform and Cocaine Anæsthesia.—PROFESSOR OBALINSKI, of Cracow, remarking the antagonism between chloroform and cocaine, determined to take advantage of it in anæsthesia for operative purposes, and has now employed the combined chloroform and cocaine method in twenty-four cases with, as he states, the most satisfactory results. He first administers chloroform by means of an Esmarch's mask until the stage of tolerance is reached, which is generally in from four to twelve minutes, with the use of from one to three drachms of chloroform. He then injects into the region about to be operated on a solution of cocaine of the strength of from three to five per cent., the total quantity of cocaine injected being from three- to five-sevenths of a grain. Even more of this might, he thinks, be safely used, both because chloroform is the best antidote to cocaine and because part of the cocaine is about to be removed from the body by the operation. After the injection no more chloroform is as a rule given, unless in protracted operations, when very small quantities are administered at considerable intervals. For this method several advantages are claimed, amongst others the following: A smaller quantity of chloroform is sufficient; vomiting is very rare; the depression on awaking is much slighter than when chloroform only is used. The only disagreeable symptoms which Professor Obalinski has observed have been excitement and throwing about of the arms in some nervous people, but as this occurs when chloroform alone is used, it is not at all certain that it ought to be ascribed to the cocaine. He recommends the combined method for extensive operations, finding the local use of cocaine usually quite sufficient to render minor operations painless.—*Lancet*, August 4, 1888.

Saccharin.—M. CONSTANTIN PAUL is loud in praise of saccharin, and thinks failures from its use are due to the fact that it is more especially a medicament than a food. He finds that after five months' use no serious gastric disturbance resulted. It is an efficient antiseptic, and in a 1 : 500 solution wholly corrects the formation of staphylococcus pyogenes aureus. He recommends its use in lavage of the stomach, and finds it especially good when

that organ is the seat of cancerous growth. He is conducting experiments and hopes to prove its value in destroying the microbes of typhoid, erysipelas and puerperal fever.—*L'Abeille Médicale*, July 16, 1888.

Treatment of Rachitis.—DR. A. JACOBI, in *Archives of Pediatrics*, says, "Rachitis due to, or connected with, *digestive disorders* demands the correction of the latter. Gastric catarrh is not frequently primary; more commonly the consequence of faulty diet; but it is in both cases the cause of anemia, and of either insufficient or abnormal secretion of both the mucous membranes and the glands. The gastric catarrh of rachitis is preëminently acid, thus neutralization of the stomach is required before every meal and between meals. Prepared chalk, calcined magnesia, bicarbonate of sodium, the several preparations of bismuth, find their proper indications in this condition. The salicylate of bismuth, animal carbon, resorcin, find their places, besides aromatic teas, in complications with fermentative processes in the intestine and excessive flatulency. When the secretions of the stomach are merely insufficient, the addition of chloride of sodium in proper quantities will facilitate the formation of hydrochloric acid. When this does not suffice, pepsin and muriatic acid, the latter largely diluted, will take the place of the physiological gastric juice; and bitter tonics, and alcoholic stimulants, also, diluted, will stimulate a normal secretion. Still the selection of a proper food forms the main part of the indications.

When, twenty years ago, C. Wegner fractured the bones of rabbits and fed the animals on minute doses of phosphorus, he found that these bones would heal in a much shorter time than those which were not so supplied. This operation induced him to employ the drug in all cases of subacute and chronic ostitis, Pott's disease, caries of the tarsus; and a great many cases led him to conclude that recovery is more readily accomplished under this treatment. Phosphorus is, by virtue of its irritating effect, when given in small doses, a tissue-builder, when in large doses, a tissue-destroyer. Thus it is that he is convinced of its tissue-building properties in other parts also. He has availed himself of this quality of phosphorus for other purposes also. It has served him well in those ominous cases, of purpura and similar processes, in which a congenital or acquired ill nutrition of the bloodvessel walls results in habitual hemorrhages.

The dose of phosphorus in these cases is from one-two-hundredths to one-one-hundred-and-fiftieth of a grain three times daily. He generally prescribes the oleum phosphoratum of the Pharmacopœia, which contains one part of phosphorus in ten parts of ether and ninety of oil. Half a minim contains one-two-hundredths of a grain. The oil solutions must not be kept in a concentrated form lest they be decomposed. A mucilaginous emulsion is the best mode of administration, for which he sometimes substituted Thompson's solution. On no account must we be tempted to try in their place the phosphates, the uselessness of which—in such cases—he has discussed extensively in a previous paper. The hypophosphites of the Pharmacopœia, with or without iron, are a better preparation than the former."

Amylene Hydrate and Chloral. — MAYER (*Therap. Monatsh.*, July, 1888) has observed that amylene hydrate is not only an hypnotic, but also a sedative, especially in diseases of the chest, promptly allaying cough. The irritation in the throat ceases before sleep is produced. He recommends its administration in doses of forty-five grains, in two tablespoonfuls of red wine with sugar; on account of its insolubility, to be recently mixed. He gives chloral similarly:

R—Chloral hydrat. . . . . 3j.
Succi liquiritiæ . . . . . 3j.
Aquæ dest. . . . . 3x.—M.
S. A tablespoonful (chloral, gr. xxiv).

Poisoning by Camphor.—A fatal case is reported, in the *Australian Medical Journal*, June 15, 1888, the victim being a girl of eighteen who had been in the habit of eating camphor. She was unconscious when seen by the physician and efforts to arouse her were fruitless. She died in convulsions. The post-mortem gave entirely negative results.

Deodorized Iodoform. — To overcome the persistent penetrating odor of iodoform, CANTRELLI adds one part of menthol and one part of oil of lavender to twenty parts of iodoform. For cleansing the hands a small quantity of an alcoholic solution of oil of lavender is added to the water.—*Corresp. Bl. für Schweiz. Aerzte*, July 15, 1888.

Salol in Catarrh of the Bladder.—ARNOLD, of Stuttgart, in the *Therap. Monatsh.*, for July, relates the case of a patient, eighty years of age, with hypospadias, in which, on account of retention of urine, from paralysis of the detrusor urinæ, catheterization twice daily became necessary from the 2d of January. The urine continued clear and of acid reaction until the 20th. At this time, there was some difficulty in passing the catheter. Notwithstanding its most careful disinfection, acute cystitis manifested itself on the 21st. The urine became of ammoniacal odor, of alkaline reaction, turbid and precipitated a sediment of bloody mucus. Fever set in, with tenderness over the bladder and with strangury. On the 24th, the temperature was normal and the pain in the region of the bladder had disappeared. In spite of rest abed, milk diet, cataplasms and warm baths, the urine maintained its abnormal condition until February 8th. Fifteen grains of salol were now given twice daily. As the drug was well borne by the stomach, the dose was increased to forty-five grains daily. To determine the action of the medicament, the urine was collected in appropriate receptacles. With the use of thirty grains a day, the urine slowly cleared up; the evening's urine was slightly alkaline and still ammoniacal; the morning's urine was slightly acid. Taking forty-five grains daily, the urine partook of a dark greenish color, but rapidly became clear; the discolored sediment, previously present, steadily diminished. On February 16th, the urine, to the last drop from the catheter, was entirely clear and acid in reaction; more urine was passed spontaneously than had been so passed in many years. On the 18th, the salol was tentatively withdrawn; the day following, the urine was again cloudy and deposited a sediment. Forty-five grains a day were then given until the 28th; the turbidity disappeared after the first dose. A second tentative withdrawal of the salol on the 29th of Feburary was followed by a result similar to that which followed the withdrawal on the 19th: turbidity and

deposit of sediment, though in less degree. Forty-five grains were daily administered until mid-March, when the patient got out of bed; from that time on, thirty grains were given until April 3d, when the dose was reduced to fifteen grains. In a few days, the urine, which had hitherto remained clear, again became turbid and deposited a sediment. At the same time the frequency of micturition was increased. Thirty grains of salol were again ordered, followed by the disappearance of turbidity and sediment. Up to the 24th of April, five ounces had been administered. The general condition of the patient was excellent and the urine of normal condition.

The efficacy of the drug is assured in this case by its tentative withdrawal. Forty-five grains a day sufficed to check the ammoniacal fermentation in the bladder and to maintain the urine clear and of acid reaction. It must be added that the salol was well borne; the tongue became clear and the appetite improved.

For Enlarged Breasts.—After stating that the internal administration of preparations of iodine decidedly reduces the women, KISCH (*Deutsch. med. Zeitung*, No. 32, 1888) recommends the following for enlarged breasts with excess of adipose tissue:

R.—Iodoform. pur. (fab. Tonk. deodor.) 1 part.
Vaselin. pur. . . . . 15 parts.
Ol. menth. pip. . . . . q. s.—M.
Ft. ung.

S.—To be rubbed into the breasts, which are then to be covered by linen moistened with warm acidulated clay:

R.—Alum. crud. . . . . 1 part.
Plumbi acetat. . . . . 5 parts.
Aquæ dest. . . . . 100 parts.—M.

And covered with rubber paper. The dressing remains twelve hours, is changed morning and evening and is continued for several weeks. So that the breasts, after the removal of the fat, may not become too much relaxed or wrinkled, the author has them rubbed with one of the aromatic spiritis and has the breasts supported by appropriate elevating bands.—*Medicin. Chirurg. Rundschau*, August 1, 1888.

Guaiacol.—It is suggested by SAHLI that this be used in place of creasote, because its composition is constant and unchangeable, while that of creasote is frequently uncertain.—*Les Nouveaux Remèdes*, Aug. 8, 1888.

A Phenacetin Exanthem.—In a case of anemia, with sleeplessness and headache, in which the bromides and antipyrin failed, VALENTIN, of Berne, administered nine grains of phenacetin at night. On two successive evenings, there was extreme heat of face, preventing sleep. The remedy was withdrawn, but renewed in a week, in doses of fifteen grains. The heat of face again occurred. During the night, it was noticed that the body was covered with red spots. At eight o'clock the next morning, the temperature was 101.5°; in the afternoon, 100¼°. The spots were profuse on arms and legs, scantier on the trunk; the majority were not larger than lentils, in part acuminated; they were darker at the centre than at the periphery; some were flat; all partly disappeared upon pressure. Headache was still present, as was the heat of face, though less marked than during the night. Urine was dark, but free from blood-coloring matter. The eruption disappeared on the following day, though anorexia and languor remained.

It may be presumed that phenacetin, like the salicylic acid compounds, like quinine and the other antipyretics, gives rise, in those specially susceptible, to a purpura-like affection, when taken in doses easily borne by others.—*Therap. Monatsh.*, July, 1888.

Serpent Bites and Hoàng-nàn.—BARTHÉLEMY records two cases of bites from poisonous serpents treated successfully by this drug. In both the symptoms were extremely alarming and the depression marked. He attributes the results to the direct excitant effect of the drug on the cerebro-spinal centres.—*Gazette Médicale*, Aug. 9, 1888.

Acetic Acid as an Antiseptic in Obstetrical Practice.—ENGELMANN (*Centralbl. für Gynäk.*, No. 27) recommends acetic acid as a disinfectant in obstetrical practice. By numerous experiments, continued over a long period, he has shown that its antiseptic virtues compare with those of carbolic acid. It has the advantage of being entirely non-toxic, so that it can be used in a more concentrated form. It has, besides, certain hemostatic properties. It possesses, in addition, the peculiarity of saturating the tissues, which other antiseptics do not, corrosive sublimate, for instance, forming an insoluble albuminate. With the mercuric chloride it shares the property of attacking metals, though not in so marked a degree that the instruments suffer. The forceps may be placed for a quarter of an hour in a three per cent. solution of acetic acid, without harm. It is unfortunate that soap is not soluble in the acid, making two ablutions necessary. The skin, however, is made soft and pliant. The author usually uses three per cent. solutions, at times five per cent., though the latter cause burning sensations at wounded surfaces, so that they are only used when septic infection already exists.—*Wiener medizin. Presse*, No. 30, 1888.

Antipyrin Subcutaneously.—VON BRINCKEN (*Therap. Monatsh.*, July) recommends the injection of a 2 per cent. solution of cocaine to prevent the pain of the subcutaneous administration of antipyrin. He has used the procedure in two cases of sciatica and in one of lumbago, always with the same result. The patients, females, however, complained of unpleasant effects from one-eighth of a grain of cocaine, faintness and nausea. The amount was reduced to one-sixteenth of a grain. This sufficed to render a sufficient area anæsthetic. The injection of antipyrin is made after three to five minutes.

Ether Hypodermatically for Asphyxia.—M. TESTEVIN reports brilliant results from the use of ether subcutaneously. He was called to see a woman, apparently moribund from charcoal fumes. Artificial respiration, flagellation, heat and cold had been used some time previous to his arrival with no success. Respiration had nearly ceased and the heart action was extremely feeble; having no electrical apparatus, he injected ether. The patient made a good recovery, although for six months after there was noticeable a weakening of the memory.—*L'Abeille Médicale*, August 6, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 1, 1888.

CREOLIN.

SUBSTANCES used as antiseptic or germicidal remedies are not only open to more exact estimation of their powers, but their effects are more evident and less dependent on subjective interpretations than any other remedial agents. For these reasons fluctuations of opinion concerning them are slow, and newly discovered members of the class do not so quickly take a prominent part in practice as do, for example, antipyretics.

These ideas arise in connection with the new antiseptic creolin, which had been in use as a disinfectant for some time before Esmarch, about one year ago, made an experimental study of it, but it had never before attracted any attention as a possible addition to the list of antiseptics. Up to that time carbolic acid, bichloride of mercury and iodoform had become firmly settled as routine antiseptics, though all had their drawbacks, and the introduction of a new one must have been difficult. Soon after the publication of Esmarch's investigations (*Centralb. f. Bact.*, etc., Bd. II., Nos. 10 and 11) followed by those of Fröhner (*Arch. f. wiss. u. prakt. Thierhkde.*, 1887), a number of independent observers took up the practical study of the drug, so that we are now in a position to come to some conclusion with regard to it.

Creolin is a product of the dry distillation of certain kinds of English coal. It occurs as a dark brown, syrupy fluid, having a strong tarry odor. It mixes in all proportions with water, oil and glycerin, and is soluble in alcohol. The watery mixtures have at first a milk-white color, but on standing a finely flocculent precipitate separates and the mixture assumes a brown color. Creolin is a "secret" preparation, and is, moreover, a mixture and not a definite chemical compound, and Liebreich has very properly called attention to the fact that under the circumstances the makers can alter its composition as they see fit. However, Fischer's investigations (*Phar. Zeitung*, 1887, 103) go to prove that at present creolin has a pretty constant composition. He found in it, in addition to a number of other coal-tar bases, eighteen per cent. of naphthalin. He could find no trace of carbolic acid, though it has been alleged that carbolate of sodium is one of the principal ingredients.

Esmarch has found that in antiseptic power creolin is equal to carbolic acid, and that soap made with it is more powerful than the common 1 : 1000 corrosive sublimate soap. The absence of toxic properties in creolin was shown by Fröhner, who fed it to dogs, in quantities of nearly two ounces, without producing symptoms of intoxication. Eisenberg (*Wiener med. Woch.*, 1888, Nos. 17, 18, 19) instituted a series of experiments, comparing creolin with carbolic acid and corrosive sublimate, and came to conclusions identical with those of Esmarch and Fröhner. Creolin gauze proved to remain aseptic for months, giving it a great advantage over iodoform.

These theoretical investigations brought out a number of communications, giving the results of clinical experiment and generally extolling the new remedy in high terms. The greatest amount of testimony is in regard to septic and purulent conditions and the treatment of accidental and operative wounds. In such cases Kortüm (*Berlin. klin. Woch.*, 1887, No. 46) sums up the advantages of creolin in these cases as uniting the beneficial properties of iodoform and bichloride, without their intoxicating power. As this observer states it, "Creolin is not poisonous, is disinfecting, limits secretion, encourages granulation and is to a certain degree hæmostatic." This opinion is concurred in by Neudörfer (MED. NEWS, 1888, vol. i. p. 210), who reports great success in erysipelas by applying solutions of creolin to the inflamed areas. Kortüm also used creolin in gynecological practice, and in the form of tampons saturated with a two per cent. solution had favorable results in cases of severe atony of the uterus.

A great number of observations have been published, showing the safe and prompt action of creolin in cases of inflammation of the genito-urinary tract, from mild urethritis to purulent cystitis. In these cases, however, the opacity of the solution is a great drawback to its continued use. For this reason its application will have to be limited to the early days of treatment, as suggested by Hiller (*Deutsche med. Woch.*, No. 27, 1888). The latter used creolin extensively in the treatment of empyema, and found it superior to all other antiseptics for that purpose. In consequence of the disadvantage named, he used creolin only in the first few days after operation, and, when the disinfectant action had been secured, returned to thymol and boric acid solutions. He afterward applied the treatment to disease of the bladder, on the recommendation of Jessner (*Deut. med. Zeitg.*, 1887, No. 102), and found it more efficient than all others, though at the same time no more irritating than 1 : 500 thymol solutions.

In various inflammatory and suppurative diseases of the conjunctiva, Amon (*Münch. med. Woch.*, No. 26, 1888) and Purtscher (*Ctlb. f. prakt. Augenhkde*, März, 1888) report the successful use of creolin solutions of a dilution of one to four in a thousand.

The internal administration of creolin has already been quite extensive. Amon, who has used it for some months, internally and by inhalation, in pulmonary tuberculosis and simple inflammatory affections of the lung with more or less secretion, gives it a high place among remedies for these common diseases. Beginning with a one-half per cent. solution and increasing to two per cent., creolin is easily inhaled. Expectoration is favored and secretion decreases rapidly under its application. In two cases of incipient phthisis the local signs disappeared on giving creolin. Amon believes that creolin is destined to take an important rank in the prophylaxis and therapy of infectious diseases.

Equally favorable are the results of creolin in diseases of the alimentary canal. Amon tried it in some mild cases of diphtheria with success. Hiller would lead us to believe that it is almost a specific for all intestinal affections. Among the conditions to which he has applied it are meteorism, typhlitis, intestinal catarrh, atony with constipation and especially typhoid fever. In all diseases of the stomach and intestine, accompanied by excessive putrefaction, creolin, according to this observer, is the best remedy, excelling naphthalin, creasote, thymol, calomel and all others. He gives creolin in doses of five to fifteen grains, usually three times a day and one hour after meals.

On account of the tarry odor of creolin it must be given in thick gelatine capsules, without any addition. A slight sense of warmth in the stomach and mild taste of creolin in the mouth were the only effects perceived by patients even when taking as much as four drachms within four days. The urine is not affected by the internal administration of creolin. On the strength of his experience Hiller advises the use of creolin in dysentery, cholera morbus or even cholera asiatica. On account of the necessity for giving the drug in capsules, it cannot be used in the treatment of infants.

Making allowance for the enthusiasm common to all early investigations with new drugs, it would seem that in creolin we have a remedy of positive value. It is difficult to reconcile our knowledge of antiseptic agents with the universal testimony as to the non-intoxicating nature of creolin, and if it is true, as Hiller suggests, that this is simply due to the physical condition in which it is exhibited (*i. e.*, in emulsion, the drops of which are absorbed with difficulty), it would be interesting to know how this is brought about, and what new product, or combination of known products of coal-tar gives rise to such a beneficent remedy.

LIKE AN ALARM OF FIRE.

The head of the Health Department of New York City has some very clear notions in regard to the great need for alertness in the management of infectious diseases. He has had occasion lately to write officially as to the imminence of yellow fever. From his letter we quote a paragraph which shows its author's confidence that his department is thoroughly equipped and disciplined. After remarking that yellow fever is not to be dreaded this year at our northern cities, he says, "If the fever should occur, however, it would be in isolated cases, with which we are prepared to deal so promptly and effectually that it will have no chance to spread. The machinery of the contagious diseases division of this department is in such condition that it can be set in motion at a moment's notice, and I am confident that the response of this department to a notice of known or suspected disease of a dangerous character would be *like that of the fire department to an alarm*. With special reference to yellow fever, we have a medical inspector constantly on duty at our headquarters. Within

five minutes after receiving a report he would be on his way to inspect it, within thirty minutes we should have his report, and immediately an ambulance and the disinfector's wagon would be despatched to the place. In an hour we should have the patient on his way to the hospital at North Brother Island."

When we reflect how much panic and harm often arise from a lack of preparation for such visitations, it is very gratifying and reassuring to read that a health official compares the readiness and discipline of his department with those of the model fire departments of our large cities, where everything is in motion at the touch of a bell.

Professor von Esmarch, of the University of Kiel, accompanied by his wife, the Princess Henrietta, of Schleswig-Holstein, and their son, Dr. Ervin von Esmarch, arrived in this country last week to attend the Congress of American Physicians and Surgeons at Washington. Last Tuesday evening the Germans in New York entertained the distinguished party at Terrace Garden. In the reception room the Schleswig-Holstein arms were conspicuously displayed with the German and American colors. There was an address of welcome to which Professor von Esmarch replied, and the Princess was presented with a bouquet. The Princess, who is an aunt of the present Emperor of Germany, upon withdrawing, handed to the Committee 1200 marks to be distributed among the Schleswig-Holstein poor of New York.

The Seventh International Congress of Ophthalmology was held at Heidelberg on August 8th to 11th. Among the Americans present were Drs. Knapp, of New York, Hasket Derby, of Boston, Harlan and Randall, of Philadelphia, and Kipp, of Newark. Professor Donders was elected President. There were also elected a number of foreign Honorary Presidents, including Drs. Hasket Derby and Knapp, on behalf of America.

A professorship of ophthalmology has been established at Copenhagen—the first in Denmark—and Dr. Edmund Hansen Grut has been elected to the chair. Grut has raised the department of ophthalmology in Denmark to an independent study, it having formerly been but a branch of surgery. All the recent Danish ophthalmologists have been students of Grut's, he having established the first eye clinic in 1863. Grut was born in 1831 and began his professional career in 1854. He has taught ophthalmology in the high school of Copenhagen since 1863.

Van Ermengen has been made Professor of Hygiene and Bacteriology at the University of Ghent.

Dr. F. Bramann, First Assistant of the Royal Surgical Clinic at the University of Berlin, in recognition of his thesis upon "Myotomy and Tenotomy, Now and in Pre-antiseptic Times," has been made a privat docent in the medical faculty of the University.

Dr. Thomas Taunton Sabine died at New York City, August 23d, aged forty-seven years. He was a prominent surgeon, and was connected with Bellevue, St. Mary's and other hospitals, but he is best known as the Professor of Anatomy at the College of Physicians and Surgeons, to which chair he was promoted in 1879, following Dr. Sands in that position, when the latter became Professor of Surgery.

Dr. Lewis Drake died at Rahway, New Jersey, on August 17th, at the ripe age of eighty-six years. For nearly sixty years he had been a leader in medicine and in public affairs. He graduated from the University of Pennsylvania in 1829.

SOCIETY PROCEEDINGS.

CONGRESS ON TUBERCULOSIS OF MAN AND ANIMALS.

Held in Paris, July 25 to 31, 1888.

July 30th—Morning Session.

(*Specially reported for* The Medical News.)

(Continued from page 220)

Third Question: Modes of Introduction and Propagation of the Tubercular Virus in the Economy. Prophylactic Measures.

Inoculation of tuberculosis by the finger.

M. Tscherning, of Copenhagen, having, some years ago, observed the inoculation of tuberculosis by the finger, performed amputation of the finger and excision of the axillary glands; histological examination showed that these glands were involved. The patient was cured. He knew of another case, a veterinarian, who was accidentally inoculated during an autopsy; his finger became involved, the parts were excised and tubercle bacilli were found, but no other lesions of the different organs.

M. Torkomian, of Scutari, was accidentally wounded during the autopsy of a tubercular patient; he developed a paronychia with axillary adenitis; but he has noticed no more accidents since, which proves that man can resist the penetration and generalization of the tubercle bacillus under certain conditions.

M. Verneuil mentioned the fact of his making the

post-mortem of a tuberculous patient with M. Maisonneuve. They were both wounded on the same day and neither of them developed the disease. Dissecting-room keepers are often affected with local tuberculosis without any fear of generalization; still, he has observed two cases of such affection producing in one a tuberculous cystitis, in the other a pleuritic and pulmonary tuberculosis.

M. CHAUVEAU also mentioned his observations. He had an anatomical tubercle for three months, and the fear of the fate of Laënnec, who died from such a lesion, made him experiment on calves, and see what effect a superficial wound, like the one of vaccination, would have. Out of five operations on calves, three had nothing, the other two presented local accidents. No general accidents were found when the post-mortem was made, a short time after. The inoculation by a superficial wound is possible, but it is not an easy method of pentration of the tubercle bacillus.

M. VILLEMIN remarked that Koch observed that the bacillus only developed in an immovable tissue; hence the movements and rubbing of the integuments are not favorable to the development of the microbe.

RESEARCHES ON THE GENERALIZATION OF EXPERIMENTAL TUBERCULOSIS.

M. JEANNEL, of Toulouse, endeavored to ascertain how long tuberculosis would remain local. He found that if an extremity is amputated twenty-four hours after an inoculation, the animal will certainly die of tubercular disease. An adenitis consecutive to tuberculosis by subcutaneous inoculation is virulent from the fifth to the seventh day. The virus passes the first chain of glands before the fourth day. The blood of a rabbit inoculated by subcutaneous grafting behaves like a virulent dilution on or before the second day. We can safely say that tuberculosis is generalized over the whole organism before its existence is manifested by visceral localization.

M. ARLOING also admitted the penetration of the bacilli into the blood and their rapid dissemination; but for tuberculosis to manifest itself in multiple places, it must find places suited to its development; and for this the penetration of microbes alone is not sufficient, the field must be prepared by the secretion of a solid matter.

ON THE RESISTANCE OF HENS TO TUBERCULOSIS BY INGESTION.

MM. STRAUSS and WURTZ, of Paris, from their experiments, showed that the gallinaceæ can be submitted to the prolonged ingestion of enormous quantities of tubercular matter without presenting any tubercular lesions; but from this we must not conclude that the introduction of tuberculosis by the intestinal canal of hens is impossible. The localization of tubercular lesions in gallinaceæ, to the digestive tract and its surroundings renders this contagion probable, but certain unknown conditions are necessary. The conclusion is that gallinaceæ are extremely refractory to tuberculosis by ingestion.

ON THE ACTION OF GASTRIC JUICE ON THE TUBERCLE BACILLUS.

MM. STRAUSS and WURTZ also referred to the experiments of MM. Chauveau, Gerlach, Klebs, Toussaint, etc., who have shown that tuberculosis can be communicated by the ingestion of tubercular matter; hence one might conclude that the gastric juice was unable to destroy the virulence of tuberculosis. M. Wisener, who made experiments on that ground, did not take the necessary precautions. He used artificial gastric juice (pepsin and hydrochloric acid) in which he placed for digestion fragments of tubercular organs, which were then inserted in the peritoneum of rabbits.

They had operated on pure cultures of tubercle bacilli, with the natural gastric juice obtained from a young dog which had had a gastric fistula for a long time. This gastric juice was very active and digested perfectly well cooked white of egg. The cultures used were made on glycerized gelatine of six weeks or two months old; the bacilli were rich in spores. They proceeded as follows: in little flasks containing one cubic centimetre of fresh gastric juice, they placed a piece of platinum wire from the tubercular culture, then these flasks were placed in a heat chamber kept at a temperature of 110° F. for variable periods, some one hour, others two, three, four, five, six, twenty-four, and forty-eight hours; after that time, about seven or eight drops of the contents of the flasks were inoculated with the hypodermic syringe in the peritoneum or subcutaneous cellular tissue of rabbits or guinea-pigs. These animals were killed at the end of thirty to forty days. At the autopsy, they found that all the animals which had received cultures, which had remained in the gastric juice for one, two, three, four, five, and six hours became tuberculous. Those that had been inoculated in the peritoneum presented a general tuberculosis of the peritoneum, liver, spleen, lungs. Those that had been inoculated subcutaneously presented a caseous abscess, rich in tubercle bacilli; while all the animals that were inoculated with tubercular cultures; which had been in contact with the gastric juice for twenty-four or forty-eight hours, remained perfectly healthy.

These experiments show that the sporulated bacilli of tuberculosis resist the action of the gastric juice of the dog for at least six hours, at the body temperature, without losing in any way their virulence. This virulence is absolutely destroyed in twenty-four hours by this same gastric juice.

In those experiments in which the pure gastric juice acts directly on a pure culture, the action of this juice must be stronger than if it acted on tubercular matters introduced into the stomach; in such cases the bacilli are imbedded in the tissues (meat, viscera) and in part protected by them. In addition, the gastric juice is diluted by the food and liquids taken, and the food rarely remains six hours in the stomach: hence we must not think that the gastric juice in man will at all protect him against tuberculosis.

FIRST CHILDHOOD AS AN ORGANIC MEDIUM IN ITS RELATION TO TUBERCULOSIS.

M. LANDOUZY, of Paris, said that tuberculosis shows or presents a variety of forms, according to the ground on which it develops at the different ages of man. One of the most interesting of these stages to consider is certainly the one starting at birth until the age of two years. In the baby, as had been already shown, tuberculosis has a greater tendency in its clinical and anatomico-pathological manifestations, to be a general disease rather than a local one; this we have had the opportu-

nity to witness, on many post-mortems, where the lesions could not explain the death, which we had to attribute to the fever.

In broncho-pneumonia of babies terminating fatally Koch's bacillus is always found; but at the autopsy we find that the disease has not gone beyond the pregranular stage. In most of these babies, measles has been the starting cause of the disease, which had been latent up to then, and he thinks that most of these measles the broncho-pneumonia ought to be ascribed to the action of tuberculosis instead of measles.

He thinks that babies are more amenable to treatment than at a later period; and especially by feeding we are able to neutralize this tendency to tuberculosis; but only boiled milk must be used. Not only does tuberculosis penetrate by the digestive tract, but also through the skin and the lungs; heredity is also a large factor; a child will be born tuberculized as another is born syphilized.

Tuberculosis in children is extremely common; in his wards he has found in fifty autopsies, one death out of three due to tuberculosis; MM. Hayem and Damaschino have obtained the same result. His conclusion is that hygiene must insist on the promulgation of laws that will regulate the feeding and hygiene of the child, and the physician himself must not give up a child because he suspects hereditary tuberculosis.

EXPERIMENTAL DIAGNOSIS OF TUBERCULOSIS.

M. VERNEUIL said that this experimental diagnosis is probably more important and more certain than searching for the tubercle bacillus with scrofulo-tuberculosis products; two or three guinea-pigs are all that is necessary, and a few sterilized Pasteur's tubes. The inoculation is made, and ten to twelve days later, when the animal even does not appear diseased, he is killed, and if the matters inoculated were tuberculous, we shall find on the peritoneum a confluent eruption of tubercles, with an extension of the disease to the spleen and liver.

M. CLADO said that tuberculosis is only visible to the microscope on the tenth day, and is well seen macroscopically on the fifteenth; the spleen, it is to be observed, presents tubercles in its interior, not on its surface. This method will also enable us to know when a tubercular abscess treated by injections of ether iodoformized ceases to contain virulent pus.

M. NOCARD said that the method recommended by MM. Verneuil and Clado can be used in veterinary medicine; but the bacteriological examination must also always be made. When we want to know the origin of substances that were in contact with the air, it is to be preferred that inoculation should be made under the skin; for outside microbes injected in the peritoneum might produce death before the experiment is completed; under the skin they produce an abscess which will discharge, but the local tuberculosis will remain; we can even detect the bacillus in the discharges coming from the suppuration of the abscess.

TUBERCULOSIS OF THE THYMUS GLAND.

Dr. A. JACOBI, of New York, read a paper on this subject; he considers this lesion to be of more frequent occurrence than is usually thought; taking the form of caseous inflammation of granular tuberculosis or again arterial tubercular lesions; when compared to the visceral tuberculosis of children, one must remember that tuberculosis of the thymus is not rare. The tubercle bacillus is found in the majority of cases.

EVENING SESSION.

MANNER OF CONTAGION OF TUBERCULOSIS BY THE DIGESTIVE TRACT.

M. BUTEL, of Meaux, claimed that tuberculosis is more often transmitted by the digestive tract than by the respiratory, and it has been proven to-day that other infectious diseases, such as typhus and malignant carbuncle, are more often produced by stomach ingestion than by any other. Vaccination of these diseases is, in fact, more certain than intravascular inoculation.

As regards tuberculosis, Jeannel has seen that the tubercular virus can penetrate the digestive tract without leaving any trace of its entrance point and yet produce pulmonary specific lesions. The tubercular virus chooses for itself a favorable part in which to develop without it being necessary that the virus should have been introduced there directly.

M. TRASBOT has observed the contamination of healthy guinea-pigs by tubercular ones which were living with them, through the digestive tract, the spleen and liver being particularly involved.

HOSPITAL HYGIENE OF TUBERCULAR PATIENTS.

M. GIORGIERI, of Florence, said that any city which does not contain special hospitals for tubercular or consumptive patients, ought to place them in well-ventilated separate buildings. The wards for these patients ought to be regularly disinfected, as well as the linen, clothing, spittoons, etc. As nurses to these patients, we ought to allow only strong, vigorous persons over thirty, who run very little danger from contagion.

TUBERCULOSIS OF THE BONES OF THE FACE.

M. LE DENTU, of Paris, observed in a man of thirty-two a primitive tuberculosis of the superior maxillary; it was first thought to be syphilitic, but specific treatment had no influence whatever. He had on the left side several suppurating fistulæ from the maxillary, and also an uneven palatine ulceration, also a suppuration of the ear and scrofulous cicatrices on the neck; he was treated with good results by the glycerole of iodoform 1 to 5.

PATERNAL TUBERCULAR HEREDITY.

M. LANDOUZY, of Paris, out of four children who died from tuberculosis, searched to ascertain whether this could be due to respiratory contamination; but the children had been separated from the father, who alone was tuberculous, the mother being well, hence this mode of contagion could not be considered. He admits the direct contagion by spermatozoa, for he has seen a woman who remained perfectly healthy give birth to a tubercular child and then have several abortions. The only explanation for these facts is the infection of the ovule by the spermatozoa.

ALIMENTARY ORIGIN OF INFANTILE TUBERCULOSIS.

M. LEGROUX, of Paris, said that cow's milk is certainly one of the most frequent ways of introduction of bacilli into the alimentary tract of children. When they have penetrated they either remain localized or generalize; the lymphatic organs agglomerate them and from

these are distributed all over the organism. They may remain latent or appear on the first occasion. On studying the point of entrance of tuberculosis in children, he has often concluded that the digestive tract was the only way, cow's milk having been given raw, without boiling; hence, let us not forget the danger of drinking raw milk. He thinks that tuberculosis can be produced by raw milk, even if the cow has a healthy appearance; and that the milk of the goat, mare, or ass is less dangerous than cow's milk.

M. Thomassen, of the Hague, said that, in Holland, veterinarians visit regularly the cows that furnish milk. If a cow is diseased, the farmer is requested to get rid of it, and the milk which is found good is sent to the city in sealed bottles.

M. Legroux asked that a commission of hygiene be formed in France, to examine milch cows, and forbid the sale of dangerous milk.

M. Landouzy asked whether veterinarians are certain of making an early diagnosis; if not, it would be more certain to recommend boiling the milk.

M. Trasbot recommended boiling the milk as the only certainty, for tuberculosis cannot be always recognized. He mentioned the fact that an ox which obtained the first prize at an exhibition was found tuberculous.

M. Nocard recommended goat's milk, if raw milk is desired, for this animal is very rarely tubercular.

M. Legroux proposed the establishment in Paris, of goat and ass stables, where such milk could be had.

M. Trasbot remarked that goat and ass's milk is very expensive, and cow's milk would be used anyhow. Hence, boiling must be insisted upon.

SEVERAL OPERATIVE INTERFERENCES ON TUBERCULOUS PATIENTS.

M. Richelot, of Paris, presented the history of a man of eighteen, who, in 1884, had a salivary fistula from Steno's duct, resulting from an abscess. He was cured eventually. In 1885, he had an enormous ganglionic swelling of the neck on the right side; all the glands were dissected out and the parts scraped, at the same time suppuration of the middle ear appeared. In December, 1885, the neck was cured, but a white swelling of the elbow made its appearance and increased rapidly. In April, 1886, the elbow was excised without complication, two suppurating cavities remained. In September, these were incised and scraped. In November, resection of a large piece of the ulna was done. In September, 1887, fistulous tracts were opened and scraped, cicatrization having taken place in November. The patient is doing very well, he has increased in weight and all lung manifestations have disappeared (in April, 1886, he had blood-streaked sputa, and physical signs at the apex of both lungs). To-day the patient appears perfectly cured.

This observation is remarkable as regards the length of the evolution of the disease, an attempt at lung involvement, without a real generalization of the disease, and the final successful result of operative interference. In rare cases such intervention will accelerate the course of the disease, auto-inoculation being produced.

ON THE CURE OF ANATOMICAL TUBERCLE BY THE THERMO-CAUTERY.

M. Barthelmey, of Paris, since 1882, has treated anatomical tubercle by the application of the point of the thermo-cautery, with numerous punctures penetrating to the depth of two millimetres, and extending one millimetre beyond the diseased spot, He has obtained very good results. He thinks, like Prof. Cornil, that this disease is due to the introduction of more than one microbe under the skin; it is usually a local cutaneous tuberculosis, but not always so. The cases he has followed have never presented visceral complications; they differ from lupus, which has given rise, on several occasions, to general tuberculosis. They also differ from primitive subcutaneous tubercular abscesses, which are always followed by a general tuberculosis, when operated upon.

Not only does this lesion present itself in the dissecting room, but he has seen it in a sister of charity who had dressed a cold abscess of the axilla; this tubercular process was three years old; he destroyed it in five sittings, one every five days. On one of his students, three sittings destroyed an anatomical tubercle of four years' standing. In twelve days he cured a tubercle of seven years' standing, and in five weeks one of nine years. As a dressing, a boracic ointment is all that is required.

ON THE CAUSE OF PAIN IN THE AMPUTATED STUMPS OF TUBERCULAR PATIENTS.

M. Guinard, of Paris, said that we often hear persons complain of pain in the extremity which has been amputated. Their pains become less frequent if we take the precaution to excise the extremities of the nerves as high up as possible. He had observed two cases in which the pain of the stump was due to tubercular lesions, situated far from the citatrix and compressing the nerves of the region. In the first case, he found a deep abscess of the iliac fossa which pressed on the nerve of the sacral plexus, and produced pain which was located in the region of the foot. The abscess was cured in fifteen days, by two injections of etherized iodoform, the pain disappearing as the abscess receded. In a second case the pain was due to a ganglionic mass in the iliac fossa, which had not suppurated, and was treated locally with good results as regards the disappearance of the pain.

Whenever a tubercular patient presents himself with pain in his stump, he looks for tubercular lesions along the course of the affected nerve; if these lesions are removed the local pain will disappear.

SURGICAL THERAPEUSIS APPLIED TO TUBERCULAR LESIONS.

M. Barette, of Paris, recommended, a week before operating, to make an injection of etherized iodoform, which will prevent the formation of pus, and keep the wall of the abscess clean for the time of operating.

CORRESPONDENCE.

OBSCURE CASE OF ABSCESS OF THE LIVER.

To the Editor of The Medical News,

Sir: The "Case of Abscess of the Liver," without the usual symptoms, which is reported by Dr. Dawson, of Charleston, S. C., in The News of August 11th, prompts me to mention briefly a somewhat similar case—similar, because of the absence of local signs.

Some twenty years since C. A., sent for me to attend him for malarial fever, as he had but recently returned from Tennessee, where he had resided for some months. I found the patient with a soft, rapid pulse, moist skin, temperature 101° and a report of "frequent chills." A diagnosis of malarial fever was made, a "blue" pill of five grains was given, followed by a Seidlitz powder, after which quinine was ordered, to anticipate the expected chill. It came, with a series of others, without any regularity, nor were they in any manner amenable to the quinine.

Rejecting my first diagnosis, suspecting septicæmia or pyæmia, as did Dr. Dawson, I instituted a searching and vigorous inquiry as to any local injury. I could find nothing, nor could I elicit any history of injury, although I repeatedly inquired. He presented no symptoms of local value, save occasional loose, clay-colored stools, the fetor of which was quite noticeable.

The case went on for some two weeks without much alteration, the patient growing weaker, more somnolent, with muttering delirium; the temperature fluctuating from 100° A.M. to 102° P.M., until death.

From the lack of salient points of any local trouble, excepting, of course, the "stools," for there was no enlargement of the liver, or jaundice, and taking into consideration the chills, I ventured to make a diagnosis of "abscess," location not known.

Assisted by a brother physician, to whom I made known my opinion of the cause of death, I made an autopsy, which revealed more than twenty distinct deposits of pus in the liver. The spleen was healthy but enlarged; the lungs were not examined. Kidneys normal, as was to be expected, since there was nothing evidenced by an examination of the urine during his sickness to implicate these organs.

Subsequently, I learned from his partner that while carrying one end of a counter he was struck in the "stomach" by one corner, and was obliged to sit down and rest for a moment. This was two or three days before his taking to the house. Had I known this during his illness much worry and speculation might have been avoided.

RALPH C. HUSE, M.D.

GEORGETOWN, MASS., August 13, 1888.

THE DINNER TO THE FOREIGN GUESTS OF THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

To the Editor of THE MEDICAL NEWS,

SIR: Some complaints having reached the Committee in regard to the distribution of invitations to the dinner to be given to the foreign guests of the Congress of Physicians and Surgeons, to be held in this city next month, I must beg the use of your columns to say that this distribution was in my hands.

The Council of the Congress having expressed themselves as averse to any elaborate entertainment on the part of the Congress, it may be said in the first place that this dinner is *unofficial* and is in the hands of the *members* of the Committee and not of the Committee.

As it was necessary, after the matter was decided upon, to act quickly in order that proper invitations might be sent to Europe and answered in time, it was not possible to arrange this distribution so methodically as might have been done had the time been longer.

It was intended that every member of the Congress—that is, every member of any of the constituent associations, should have an opportunity to subscribe.

Some circulars were sent directly by me and some of them by such representatives of the associations as I could most readily get at. It is possible that there may have been accidental omissions, and it is more than possible that at this season, when so many gentlemen are absent from home, some invitations have gone astray; another possibility, which we know to have been in some cases an absolute fact, is that circulars have been placed in the waste-paper basket.

This note is intended as an invitation to every member of all the associations composing the Congress of American Physicians and Surgeons, who wishes to do so, to send his subscription of twenty dollars to Dr. S. C. Busey, 1545 I St. (N. W.), Washington, D. C., for a dinner to be given at Willard's Hotel, in this city, on Monday, September 17th, at 7.30 P. M.

I am very respectfully,

ROBERT T. EDES.

WASHINGTON, August 21, 1888.

NEW INVENTIONS.

A NEW INTRA-UTERINE ELECTRODE FOR USE IN THE APOSTOLI OPERATION.

BY G. BETTON MASSEY, M.D.,
OF PHILADELPHIA

AFTER many experiments with different forms of electrodes for the application of powerful currents to the interior of the uterus, I have finally settled on the form shown in the cut, which I think is an improvement on those employed by Apostoli and other operators.

The Apostoli instrument consists of a sound, sliding within an insulating cover of hard rubber or celluloid (the latter material being preferred by him) and capable of being fixed solidly in the handle with any desired exposure of the end. The disadvantages of this method of insulation are:

(1) The impossibility of covering part of the curved portions of the sound by the unyielding cover when we wish to protect the neck of the uterus from cauterization. It is possible that the cases of atresia that Apostoli admits have occasionally followed his negative cauterizations were due to unnecessary action in this situation, as it is an accident that has never occurred to me since I have been in the habit of protecting the cervix. This protection of the cervix and concentration of the current action upon the interior of the corpus alone is impossible if the sheath is made of rigid material, and were it possible, the abrupt increase of calibre at the end of the cover would render the proper insertion of the sound impossible in many cases.

(2) The inflammable nature of a hard rubber or celluloid cover renders a cleansing by the alcohol flame impossible, and as its calibre is small, other means of sterilizing it are more or less unreliable.

The device that has successfully obviated these difficulties in my hands is simply the fusing upon the electrode, after it has been properly bent, a sufficient quantity of pure gum shellac. This makes a perfectly homogeneous instrument, the highly insulating material adhering firmly to the metal and presenting a smooth, hard

surface. It is accomplished by heating the sound over an alcohol lamp until all septic material has been incinerated. It is then hot enough to take the coating of gum from a solid piece held in the hand. The first coating is too thin and should be added to by fusing more shellac and dropping it upon it, and the whole is then brought to a uniform thickness by a gentle reheating over the flame. This leaves a smooth, highly insulating covering, that adheres tightly to the sound and shades off in thickness at the bare end so gradually as readily to admit its passage wherever desired.

Before each subsequent operation this electrode may be thoroughly sterilized and any accidental breaks closed by a reheating of the end in the alcohol flame and a fusing of at least two or three inches of the cover. Before the reheating the proper depth of exposure of the end should be determined upon and the necessary curve imparted to it.

This coating is only adapted to the rigid-shanked Simpson pattern, as shown in the accompanying cut, as after the parts are once covered there should be no danger of bending, which would give rise to unpleasant leaks, the material being quite brittle.

As to the electrode itself, it is sufficient to say that the first two and a half inches at the point are of platinum, to adapt it for use with the positive pole. The flat handle of hard rubber, which seems to have been overlooked by electrode-makers heretofore, fulfils the same important functions as in ordinary sounds.

I have used as much as 400 milliampères repeatedly with this form of electrode without the cover being affected in any way, but its brittleness would doubtless render it an unsafe covering for the electro-puncture needle.

1706 Walnut St.

NEWS ITEMS.

The Yellow Fever Quarantine.—Surgeon-General Hamilton, with the approval of the Secretary of the Treasury, to-day issued a circular promulgating the following regulations for the prevention of the spread of yellow fever from certain infected places in the State of Florida:

In accordance with the act of April 29, 1878, and appropriation acts, authorizing the maintenance of quarantine at points of danger, the following regulations are framed to assist in the work of preventing the spread of yellow fever, now prevailing as an epidemic in certain towns in the State of Florida:

1. A camp of refuge for persons from infected places in Florida is hereby established, to be under the command of Passed Assistant Surgeon Guitéras, on the south bank of St. Mary's River, near the crossing of the Savannah, Florida and Western Railroad, to be known as Camp Perry. Temporary quarantine stations are hereby established, under the direction of Surgeon Hutton, Marine-Hospital Service, near Waycross, Ga., and Live Oak, Florida. Those at Dupont, Georgia, and Chattahoochee River Junction are hereby discontinued.

2. At the station aforesaid an inspection will be made of all persons, baggage, mail and express arriving by rail from points south, and in case of arrival of any person, mail, baggage or express matter capable of conveying infection, coming from an infected place or a place not known to be healthy, as shown by recent inspection reports, then such person shall either be returned to the original place of embarkation or to Camp Perry, at his or her option, and the baggage of such person shall be held for fumigation, and fumigated under the direction of the Railway Mail Service, under orders already issued by that service.

3. All persons arriving at Camp Perry will be under the orders of the commanding officer, and will not depart the camp, without permission, until ten days shall have elapsed from the date of their departure from an infected place. A special daily train will run between Jacksonville and Camp Perry for the purpose of conveying persons from Jacksonville, and such other business as may be incident thereto; and, at the expiration of the detention period, they will be taken to Waycross and then allowed to proceed to their destination without further detention.

4. Railway agents, conductors or other persons in charge of railway trains south of and including those of the Savannah, Florida and Western Railroad will not receive persons from infected places on board trains, except to the refuge camp, as provided in paragraph 1 of this circular, and sleeping cars will not be allowed to proceed south of Waycross, Ga., until the cessation of the epidemic.

An additional refuge camp, under the same regulations as those governing Camp Perry, will be established in the mountains of North Carolina (the site hereafter to be determined) as soon as practicable.

The Congress of American Physicians and Surgeons.—In view of the fact that frequent inquiries are made of the Committee of Arrangements by medical men and others in regard to the character of the organization now known as The Congress of American Physicians and Surgeons, which will hold its first triennial session in Washington, September 18, 19 and 20, it is deemed proper to state that several years ago the American Surgical Association passed a series of resolutions declaring it expedient that the special medical societies in this country should adopt some plan of organization by which they should be brought together at certain stated periods, and invited the other societies to coöperate with it in perfecting such a scheme. This invitation was accepted by the several societies, and in October, 1887, a committee of conference, composed of delegates from each of the societies, assembled in Washington and agreed upon a plan of association, which was subsequently considered and accepted by the societies constituting the Congress as now organized. This plan consists simply of the agreement that the medical societies named shall hold their usual annual meetings at the same time in that city every third year, and that an executive committee, composed of one member of each society accepting the agreement, shall

arrange for one or more general meetings for the consideration of such medical subjects, by such physicians and surgeons as it may select, to be followed by such general discussion as time may permit. There is no membership in the Congress proper. Membership belongs exclusively to the several societies constituting the Congress. Each society prescribes its rules for admission of candidates, and transacts its business according to its own method. The Congress, as such, does not in any manner interfere with the autonomy of the several constituent societies.

The guests are men of distinction in some special department of medical science, who have been invited by some one of the constituent societies to attend its meetings, and perhaps to present a paper on some chosen subject. They are guests of a society, not of individual members.

The meetings of the Congress and of the societies will be open to the profession; but the privilege of taking part in the discussions will be limited to the members, guests and those who may be invited to do so by the societies respectively. The invitation to attend the meetings and engage in discussion will not, however, entitle one to the privileges of a guest.

Members and visitors must avail themselves of the ordinary excursion rates of railroad fare.

The Postmaster has arranged facilities for the distribution of the mail at the office of registration, in Willard's Hotel. Letters must be addressed to "The Congress of American Physicians and Surgeons, Washington, D.C."

It may be added, that the Committee of Arrangements decline to make any provision for, or to have anything to do with, any exhibit of pharmaceutical preparations and medical and surgical appliances.

The Progress of Surgery during the last Half Century was the title of Sir George Macleod's Address in Surgery at the late Glasgow meeting of the British Medical Association. The most distinguishing features of the period under review, he said, have undoubtedly been anæsthetics and antiseptics. They are both "epoch-making" discoveries. Each has done almost as much for surgery as the discovery of hæmostatics, and when combined may, he thought, be said to excel even steam and electricity in their gracious benefits to mankind. Though from the earliest times men sought for the means of allaying pain during operation, and numerous imperfect methods had been tried to effect it, yet the statements of Velpeau, published in 1839, may be taken as expressing the opinion held seventeen years before the great discovery—"All research for an agent to destroy pain in operations is a mere chimera and unworthy of further consideration." Suddenly, however, the riddle was solved by one who, recalling the experiments of Humphry Davy with nitrous oxide and sulphuric ether, dimly perceived the use they might be put to in surgery. Whatever credit in this matter may belong to the unfortunate Horace Wells, it was really Mr. Morton, who worked out the practical application of ether, and in the theatre of the Boston Hospital may still be seen the sponge by which it was administered on that memorable October morning in 1846. Many of us can still recall the enthusiasm which that discovery evoked, and the unbounded anticipations which it suggested.

Of antisepsis, he said, that notwithstanding all the criticism and opposition which it has met with, the fundamental principles on which it rests remain, in his humble opinion, unassailable, and that it has led to practical results (not alone in its immediate effects, but in the discussions and studies which it has produced) which have, in an extraordinary degree, widened the domain of our art, diminished the sufferings, and saved innumerable human beings.

The practical application of aseptic surgery has amazingly augmented the importance and value of the surgeon's services, as the advantages of that system cannot be secured without wide knowledge and great assiduity on his party. Perfect drainage; entire rest, both mechanical and physiological (which includes the avoidance of all tension in the wound), and such attention to hygienic and constitutional conditions as will maintain and increase the resistance of the tissues, and of the general system, to the invasion of disease, are essential to the "system" on which wounds are now treated, and demand the most assiduous care from the practitioner. Of the many germicides which have been used I undoubtedly prefer the bichloride of mercury, which, with the soft alembroth lint and Gamgee elastic absorbent wool, are most perfect local applications. Dry and elastic dressings (the many medicated and absorbent wools, cottons and lints now in use) have been, in my experience, most valuable advances in wound management. With reliable antiseptics—that is, agents which are capable of destroying the septic germs, or, at least, inhibiting their development, without, at the same time, causing local or constitutional harm—and with a scrupulous attention to details which must never flag, almost every organ and cavity of the human body may be, and have been, invaded, in some cases, perhaps, with too confident temerity.

Of the treatment of stone of the bladder, he said, for over fifty years lithotrity has been gaining ground, and since 1878, when Bigelow introduced his litholapaxy, the whole practice has been so changed as to constitute an entirely new operation. The greater capacity of the urethra which Otis demonstrated; the immensely greater tolerance of the bladder to the presence of instruments which Bigelow showed to exist; and the improvements in the apparatus for breaking up and removing the fragments, together with the use of anæsthetics, have all combined to establish the triumph which has undoubtedly been achieved. The extension to young boys (even to infants, as has been lately shown) of the advantages of lithotrity has also been attained, so that great size and extreme hardness are almost the only obstacles which now stand in the way of its universal application. With a better knowledge of the causes which produce calculus, an earlier recognition of its presence, and the modern system of removing it entirely at one sitting, it may be said that one of the greatest of human calamities has been nearly overcome.—*British Medical Journal*, August 11, 1888.

Re-implantation of Bone.—After his Address on the Surgery of the Brain (see THE MEDICAL NEWS of Aug. 18), at the recent meeting of the British Medical Association, Dr. Macewen gave a demonstration of cases so remarkable that it alone would suffice to render the Glasgow meeting memorable in the annals of surgery. Many of the patients whose cases have been described in the address were present, but the many eminent surgeons who attended were greatly interested also in the examples

of re-implantation of bone; the head cases afforded many instances, but the most remarkable was a boy, in whom the whole shaft of the humerus had been reformed from grafts, forming a useful link. The audience was large, and Dr. Macewen was loudly applauded and received numerous congratulations on his brilliant results. —*British Medical Journal*, August 11, 1888.

Entertainment of the Americans at the Meeting of the British Medical Association.—A number of British medical men, who visited the United States last year on the occasion of the International Medical Congress at Washington, performed a graceful act of courtesy and gratitude at Glasgow, last week, in the shape of a banquet to the American visitors to the Association meeting. The banquet took place at the Bungalow, in the Exhibition grounds, with Mr. Lennox Browne in the chair. Upward of fifty persons took part in the festival, comprising the majority of the Americans then residing in Glasgow.—*Medical Press*, Aug. 15, 1888.

Residential Buildings for Medical Students.—The medical staff of Guy's Hospital, with the consent and full assistance of the governors, have decided to build a residential college for the students. This will be erected on premises within the hospital precincts, on ground on which the first Nonconformist place of worship in London was situated. It is intended for the reception of sixty men, amongst which number will be included the resident staff of the hospital, the house surgeons, house physicians and others, who will be in telephonic communication with the hospital buildings. Every convenience will be provided and amongst other things a gymnasium will be included, for the use of the residents; this is as it should be. The building is calculated to cost £20,000, the whole of which has been already subscribed.—*Lancet*, July 28, 1888.

"Good Enough for the Hospitals."—A Spanish magistrate, shocked and exasperated by repeated food adulterations, has issued a proclamation, aflame with righteous wrath, that "all wines, groceries and provisions which, upon analysis, are proved to be injurious to health, will be confiscated forthwith and *distributed to the different charitable institutions.*"—*Boston Journal of Health*, Aug. 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 21 TO AUGUST 27, 1888.

VOLLUM, EDWARD P., *Lieuteant-Colonel and Surgeon* (U. S. Army).—Leave of absence extended two months.—Par. 17, *S. O. 192, A. G. O.*, August 20, 1888.

ALEXANDER, RICHARD H., *Lieutenant-Colonel and Surgeon.*—Detailed as a member of the Board to meet at San Carlos, Arizona Territory, August 28th, to select a site for a new post at that place.—Par. 1, *S. O. 44, Division of the Pacific*, August 15, 1888.

SMITH, JOSEPH R., *Medical Director and Surgeon, Department of Dakota.*—To inspect Forts Pembina, Totton, Buford, Abraham Lincoln and Yates, Dakota Territory.—Par. 4, *S. O. 77, Department of Dakota*, August 13, 1888.

HEGER, ANTHONY, *Surgeon* (U. S. Army).—In addition to his other duties, to attend to the duties of the Medical Director, Division of the Atlantic, during the absence of Colonel Charles Sutherland. —Par. 4, *S. O. 170, Division of the Atlantic*, August 18, 1888.

WRIGHT, JOSEPH P., *Major and Surgeon* (U. S. Army).—Detailed as a member of the Army Retiring Board, Fort Leavenworth, Kansas, vice A. A. Woodhull, Major and Surgeon, U. S. A., relieved.—Par. 10, *S. O. 190, A. G. O.*, August 17, 1888.

WOODHULL, A. A., *Major and Surgeon* (U. S. Army).—Relieved from duty with the Army Retiring Board, Fort Leavenworth, Kansas.—Par. 10, *S. O. 190, A. G. O.*, August 17, 1888.

AINSWORTH, FREDERICK C., *Captain and Assistant Surgeon* (U. S. Army).—To proceed to Atlanta, Georgia, and inspect the new Army Hospital at that place.—Par. 18, *S. O. 192, A. G. O.*, August 20, 1888.

MAUS, LOUIS M., *Captain and Assistant Surgeon* (U. S. Army). —Having completed rifle practice at Camp S. B. Luce, Fisher's Island, New York, to return to his proper station (Fort Schuyler, New York Harbor).—Par. 3, *S. O. 171, Division of the Atlantic*, August 20, 1888.

OWEN, W. O., Jr., *Captain and Assistant Surgeon* (U. S. Army, Fort Leavenworth).—To report for temporary duty to the Commanding Officer, Fort Gibson, Indian Territory.—Par. 1, *S. O. 104, Department of the Missouri*, August 20, 1888.

MASON, CHARLES F., *Assistant Surgeon* (U. S. Army).—Ordered to Fort Washakie, Wyoming Territory, for duty.—Par. 5, *S. O. 190, A. G. O.*, August 17, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING AUGUST 25, 1888.

SIMONS, MANLY H., *Surgeon*.—Detached from the "Constellation," and ordered to the Naval Academy.

RUSSELL, A. C. H., *Passed Assistant Surgeon.*—Detached from the "Constellation," and ordered to the Naval Academy.

DICKSON, S. H., *Passed Assistant Surgeon.*—Detached from the Marine Barracks, Washington, D. C., and ordered to the U. S. S. "Richmond."

CORDEIRO, F. J. B., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Mohican."

FARWELL, W. G., *Surgeon.*—Detached from the U. S. S. "Saratoga," and ordered home to wait orders.

DICKINSON, DWIGHT, *Surgeon.*—Detached from the U. S. S. "Portsmouth," and ordered home to wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING AUGUST 27, 1888.

SAWTELLE, H. W., *Surgeon.*—Directed to proceed to San Diego, Cal., and inspect Service at said station, August 17, 1888.

HUTTON, W. H. H., *Surgeon.*—To proceed to Way Cross, Ga., and assume charge of inspection and fumigation stations, August 17, 1888.

URQUHART, F. M., *Passed Assistant Surgeon.*—To report to Surgeon Hutton for special duty, August 19, 1888.

GEDDINGS, H. D., *Assistant Surgeon.*—Appointed an Assistant Surgeon August 18, 1888. To report to Surgeon Hutton for special duty, August 19, 1888.

WERTENBAKER, C. P., *Assistant Surgeon.*—Appointed an Assistant Surgeon August 18, 1888. Assigned to duty at the port of Norfolk, Va., August 20, 1888.

STONER, J. B., *Assistant Surgeon.*—To proceed to Charleston, S. C., for temporary duty, August 20, 1888.

GUITÉRAS, JOHN, *Passed Assistant Surgeon.*—To proceed to St. Mary's River, Fla., establish and take command of refuge camp at that point, the camp to be known as Camp Parry, August 20, 1888

ORIGINAL LECTURES.

ON THE DIAGNOSTIC VALUE OF FREQUENT MICTURITION.

A Clinical Lecture.

BY F. R. STURGIS, M.D.,

PROFESSOR OF VENEREAL AND GENITO-URINARY DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SURGEON TO THE CHARITY HOSPITAL, R. I. (VENEREAL DISEASES).

GENTLEMEN: One of the most important symptoms in the diagnosis of many genito-urinary affections is the frequency of micturition, which, it must be clearly borne in mind, is a symptom only and not a disease in itself. What I particularly wish to direct your attention to in this lecture is the importance of this symptom as a diagnostic sign. Speaking broadly, it may be due to diseases of the urethra and its appendages, to diseases of the bladder and of the kidneys; but first let us consider the bearing which it has upon diseases of the urethra.

In the first place, as regards gonorrhœa. During the early stage of this disease—that is to say, within the first few days of its duration—a not infrequent symptom, besides the slight discharge which ensues, is a desire to pass water frequently, a symptom which the surgeon may, perhaps, ascribe to some affection of the bladder, if his attention has not been called to the fact that this may be simply a reflex from irritation elsewhere, and not due to any disease of the bladder itself.

If frequency of micturition be due to disease of the bladder, it will probably come from some acute inflammation, and as such would be attended or accompanied by pus in the urine. In order to test this point the patient is made to pass his water and the sediment which forms is examined for pus. But it does not always follow that, because pus corpuscles are found in the urine, that necessarily the pus comes from the bladder; hence, if the water be passed all at once in one receptacle, it will be impossible to decide whether the pus comes from the urethra, or whether it comes from the bladder, or from both. This point can, however, be very easily determined in the following manner: Make the patient pass his urine in three separate glasses, one to represent the first third that is passed, the next the second third, and the rest the remaining third. If the pus come from the anterior portion of the urethra, it will be found in the first quantity that has been passed; if in the deeper part of the canal, sometimes in the first, but, for the most part, in the second; and if from the bladder, only in the last; and the reason for this is obvious. If the bladder be affected, the pus, being heavier than the urine, settles down to the lower and most dependent portion of the bladder, and the fluid which is first passed would be clear if the pus comes from the bladder; if, however, the first portion of urine passed contains pus, it comes from the anterior portion of the urethra, as that is the portion which is flushed by the first passage of urine. During the middle third of urination the deeper muscles of the urethra come more into play, and what pus there is is then dislodged from the urethra, by the water which is passed. In the latter third of micturition the deeper muscles and the sphincter muscles of the bladder press out the pus in the last portion of the urine which is passed, so that in that part any matter which is contained in the bladder as a result of inflammation would be seen.

Another source of frequent micturition is due to inflammation of the deeper part of the urethra, the membranous and prostatic portions, and, in cases of clap, as the disease extends the inflammation of the mucous membrane lining the deep and prostatic urethra produces a flow of pus similar to what takes place in the anterior portion during the earlier stage of the clap, and this, in rotation also gives rise to a frequent desire to void the urine, which usually comes in small amounts at a time. It is also accompanied by an inability to retain the water the moment the desire to micturate is felt. As the disease progresses and involves the neck of the bladder, these symptoms become still more aggravated, so that the desire to pass water in acute inflammation becomes almost incessant, and the ability to retain it becomes also less.

But, in addition to the acute catarrhal inflammation of these portions of the genito-urinary tract, there are other causes which play a part in producing this symptom, and one of the most frequent of these is the existence of a stricture, particularly of the variety known as "irritable stricture," seated anywhere in the canal. An irritable stricture seated near the meatus will oftentimes produce reflex irritation to such an extent as to lead to repeated attempts to evacuate the bladder. The next point is when the stricture is seated three and a half inches in the canal not far from the region of the bulb where the mucous membrane is very apt to be irritated, more so, perhaps even, than when the stricture is seated further back. In my experience strictures seated in the deeper part of the canal are not frequently attended by an irritable condition, and very seldom give rise to much trouble in frequency of micturition. Then, as we progress further back, the prostatic portion of the urethra and the neck of the bladder are very seldom the seat of any trouble, apart from acute inflammatory affections, which would induce this condition of affairs. But the prostate itself may be the cause of this symptom from hypertrophic enlargement or the formation of an abscess. In young adults hypertrophy of the prostate as an idiopathic affection is extremely rare, and if this organ be attacked by acute inflammation, ending in suppuration, the first symptom would be an inability to pass water, a retention, so to speak, rather than a desire to pass frequently; but after the bladder has become full the "besoin

d'uriner" becomes so urgent that the water is passed frequently and in small quantity. In this case, however, it is not due to inability, on the part of the bladder, to retain the water, but rather as the result of an over-full bladder; in other words, the frequency of micturition, under these circumstances, is due to an overflow, and would, of course, necessitate the use of a catheter to relieve the distended bladder.

Idiopathic hypertrophy of the prostate seldom comes on until after middle life—that is to say, between fifty and sixty years of age—and the accompanying frequency of micturition is probably due to a reflex irritation and to pressure upon the neck of the bladder by the enlarged prostate. The patient is then obliged to pass water more frequently than he has been in the habit of doing, not only during the daytime, but also at night; and this desire is accompanied by no pain or uneasy sensations, such as we find to be the case when the cause of this symptom is due to an acute inflammation, either of this portion of the genito-urinary apparatus or of the urethra.

As I have said, gonorrhœal cystitis is one of the causes of frequent micturition, but, besides that cause, cystitis due to other causes, such as cold, stone in the bladder, ulcerations of the mucous membrane and polypus of the neck of the bladder, will also produce the same train of symptoms, viz., an uneasy sensation about the neck of the bladder, a desire to pass water frequently, unattended by pain or tenesmus.

When the cystitis is due to the presence of stone, if the stone lie free in the bladder there will oftentimes be a strong desire to pass water and yet an inability to pass more than a few drops, perhaps, at a time. Sometimes this condition of affairs is varied by the stream coming in full size and in tolerable amount after the patient has changed his position, or has strained a ltttle, caused, probably, by the stone rolling away from the vesical end of the urethra and thus allowing an exit to the urine, and the few drops which are passed at first are due to the occlusion of the mouth of the bladder by the stone rolling in front. Of course, other symptoms of stone in the bladder, such as pain referred to the head of the penis, pain shooting down the inside of the thighs, would at once direct your attention to the possible existence of stone, and cause you to make an examination to settle that point.

If the stone be seated in the cul-de-sac of the bladder, or if it be encysted, the only symptom will be a sensation of uneasiness and weight in the bladder and a desire to pass the water more frequently than usual, but without any of the other symptoms of a stone, viz., occlusion or stoppage of the stream of water.

A tumor of the bladder will oftentimes cause the same condition of affairs, and I have seen one case in which a varicose condition of the veins about the neck of the bladder produced, in addition to the hæmaturia, a frequent desire to pass water, which was nearly always accompanied, toward the end of the act of micturition, by an amount of blood, varying from a few drops to a drachm or two at a time. This case was relieved by a perineal section and cystotomy, which relieved the varicose condition, and with it the urgent desire to pass water.

Ulcerations of the mucous membrane of the bladder will also sometimes induce the same condition of affairs, but in a less degree than when the disease is due to the causes to which I have already called your attention.

The presence of pus in the bladder, no matter what the cause may be, seems to produce a desire to pass water, and we find oftentimes that this symptom accompanies the existence of pyelitis. The pus coming down from the kidney through the ureters is deposited in the bladder, and there for some reason or other seems to act as an irritant, not sufficient, however, to excite an acute inflammation. but simply the desire to micturate more frequently than normal. The other symptoms of pyelitis, viz., pain about the renal region, the enlargement, etc., if the disease has sufficiently advanced to that stage, will put you on the track of the true cause of these symptoms.

Another point, also, to which I wish to call your attention, and which I have already incidentally spoken of, is the fact that a repeated micturition or a continued dribbling away from the urethra is sometimes due, not to an inability on the part of the bladder to retain its contents, but rather to an over-distention of this organ, and this is sometimes the case in atony of the bladder, due either to over-distention from the habit which some people have of retaining their water for a great length of time, or to paralysis of this organ, as the result of a paraplegia. In those cases the natural irritability of the bladder is destroyed and the urine accumulates until the viscus can hold no more. It then gradually leaks away, and the patient at first only notices that he has to pass his water more frequently than usual, and that what is passed comes away only in small quantities. The reason of this, from what I have already said, is perfectly plain. What comes away is the surplusage which the bladder cannot contain. As soon as that surplus is reduced to the standard which the bladder can hold no more comes away, because the contractile force of the bladder is lost and no more passes until the over-distention point is reached. The desire to urinate then comes on, and a little more is passed again, and so it goes on until later on the bladder, being unable to contract any longer upon its contents, the urine dribbles away continually. This symptom would, of course, at once attract your attention, but the earlier one of frequent micturition might, perhaps, not, and you would refer it to some other than its true cause.

Diabetes is also another cause for this condition, and is probably due to the large amount of urine which is secreting, and which finds its way into the bladder, filling that organ faster than it does in the normal condition, and so necessitating a more frequent desire for urination.

Besides pyelitis, other affections of the kidneys may also be the cause of frequent urination, and foremost among these stands chronic interstitial nephritis. This disease, characterized usually by a pale, slightly turbid urine, frequently gives rise to irritation of the bladder without inducing any disease in that viscus. The urine, when examined, is found a little below the normal standard as regards specific gravity, and usually contains albumen and casts. Both of these, however, are frequently absent. There is nothing peculiar in the appearance of the urine, and the only thing which attracts the patient's attention is the fact that he has to get up several times during the night to pass his water. An examination of the urethra and the bladder gives negative results and the urine, when examined, may also show but little

to point to the true cause of the disease. If albumen and casts are present, of course a diagnosis may speedily be arrived at; but in many instances both of these symptoms are absent, and then the main points in the question of diagnosis are the continued low specific gravity and the diminished daily amount of the urine which is passed. This variety of renal disease is oftentimes one of the most difficult to detect, owing to the fact that the symptoms are so entirely of a negative character.

Frequent urination may also be induced by what is known as neuralgia of the vesical neck, or of the bladder itself, as well as neuralgia of the urethra. This peculiar disease is attended by all the symptoms either of acute irritation of the neck of the bladder, or else of stone in the bladder, so much so that patients have sometimes been repeatedly sounded for stone, under the impression that the symptoms were due to that cause. It is attended not only by a frequent desire to pass water, but also by most distressing pain, usually immediately after the act of micturition, and which extends, in varying degrees of intensity, from the meatus to the neck of the bladder. At times the patient may be entirely free from pain and discomfort and pass his water apparently with no irritation and with no excessive frequency; at other times all these symptoms will be aggravated, and the patient will be called upon to empty his bladder, especially during the day, several times in the course of an hour, the amount passed at times being small in quantity and attended with extreme irritation. During the night, when the patient is asleep, the frequency is very much diminished, but toward morning it commences again, calling the patient up from his bed several times before he finally rises to dress. The urine when tested is perfectly clear and normal in all respects. Examination of the urethra fails to detect any particularly sensitive point or the presence of stricture. The bladder when examined fails to show any evidence of disease, and yet all these symptoms will continue, often in a most distressing manner, without any apparent cause.

This neuralgic condition is frequently associated with neuralgia of other parts of the body, but it sometimes seems to be confined alone to the genito-urinary apparatus. In the male subject the testicles will oftentimes be affected, but usually in an inverse ratio to the irritation of the bladder. Thus, if the symptoms of the bladder seem to be relieved, the neuralgia of the testes comes on with greater intensity, and *vice-versa*.

The question of the treatment, of course, varies with the cause which induces this symptom,—for remember that this condition of frequency of micturition is only a symptom and nothing else,—and it oftentimes is an important one, because it may be due to serious disease as well as to disorders of light character. If it be due to gonorrhœa, especially during the earlier stages, the use of injections, and notably the astringent injections, will relieve it perhaps as quickly as anything else. And although the frequency may be great, it is better to commence at once with the use of injections, especially with the sulphate or acetate of zinc, than it is to treat the case internally by the use of balsams or oils. In several instances I have been able, by applying a solution of 10 or 20 grains of the nitrate of silver solution directly through the endoscope, to relieve this symptom when it had been very marked indeed. And let me here repeat what I told you when speaking in a previous lecture, of the use of the endoscope in the treatment of urethral affections, that the urethra will tolerate a strong solution of nitrate of silver if it be confined directly to the point diseased, where an injection of half or quarter of the strength would produce a great deal of irritation in the canal. This is only repeating in the anterior portion of the canal what we sometimes find to be of benefit in the deeper portion of the urethra for the treatment of cystitis, of which I shall speak in a few moments. When the disease is in the deeper part of the canal—that is to say, near the prostate or neck of the bladder—injections will oftentimes relieve the symptoms, and it is here also that the topical applications through the endoscope are peculiarly of service. Many observers have been able to control an acute attack of cystitis, and even an epididymitis by the injection of a few drops of a strong solution of nitrate of silver to the deeper part of the canal by means of a deep urethral syringe. I myself prefer very much making the application through an endoscope, because the application can be confined to the diseased part absolutely, and there is no danger of the solution flowing over sound tissue, and in these cases I oftentimes make an application of quite a strong solution; seldom under forty grains to the ounce, and I have in some cases used a saturated solution.

If the symptom be dependent upon stricture of the urethra, the removal of the stricture by any one of the methods which are in vogue, and which I shall discuss in a future lecture, will relieve the symptom by removing the cause; but it sometimes happens that even after a stricture is thoroughly divided and large sounds are passed into the bladder, this symptom will continue. I recall one case particularly, which happened to me lately, in which I operated on a patient for irritable stricture of the urethra 5½ inches deep. The operation was by divulsion, and the stricture was split to a 32 F., the fullest size which his urethra was capable of admitting. Previous to the operation there had been a slight tendency to frequency of micturition, which seemed to increase after the sounds had begun to be passed regularly. After it was evident that the sounds would not relieve this condition, I examined him with an endoscope and found a congested and irritable point just behind his stricture. I made three applications of a 40 grain solution of nitrate of silver, with the result of relieving him entirely of his desire to pass water frequently, and the sounds were used afterward in the further treatment of the case, but at no time did this symptom of frequency of micturition recur.

If the disease be due to prostatic enlargement, but very little can be done. Iodide of potassium has been spoken of favorably in relieving this symptom in such cases, and it is worth perhaps a trial at your hands. Judging from my own experience, you will not have such brilliant results as you might hope for from reading the reported cases.

Where the disease is due to gonorrhœal inflammation of the bladder and prostate the use of the balsams, the oils of sandalwood and cubebs, small doses of turpentine, and suppositories of belladonna and opium should be tried, and in the course of a short time, as the inflammation subsides, this symptom will pass off.

When due to a varicose condition of the bladder or tumors within this viscus, surgical interference is the only thing to be resorted to, either by perineal section or by the suprapubic operation.

Frequent washings out of the bladder have been recommended in cases of cystitis, but I am inclined to believe that more harm than good has been done by such methods of procedure. If you decide to wash out the bladder, remember not to do it too frequently and, also, never to inject a large amount of water at a time. Four or six ounces of water thrown in is all the bladder will probably contain with any degree of safety, and the operation should always be done very slowly and the water allowed to run out without filling the bladder to its fullest extent. I need hardly say that in these cases the water should be warm and never cold.

When you have to deal with pyelitis as the cause of the disease, surgical instruments will not be required unless the kidney has become the seat of abscesses and so thoroughly disorganized as to require removal. Under these circumstances nephrectomy is the only thing to be done.

The treatment of chronic interstitial nephritis and diabetes comes more within the domain of the professor of clinical medicine than mine, and so I shall say nothing here in regard to it.

SEPSIS OF THE NEWBORN AND DIPHTHERIA OF THE NEWBORN.[1]

By J. LEWIS SMITH, M.D.,
CLINICAL PROFESSOR OF DISEASES OF CHILDREN, BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

SEPSIS OF THE NEWBORN.

The manner in which sepsis or septicæmia occurs is sometimes obscure. Leube, in 1878, relates two cases (*Deutsch. Archiv für klin. Med.*) in which the examination failed to disclose the source or mode of infection. He designates such cases cryptogenetic, expressive of the unknown or occult origin. Wunderlich and Schützenberger allude to similar cases. But in sepsis of the newborn it is the common and apparently correct belief that the poison of sepsis usually enters the system at the umbilicus. The cases which I am about to relate are in harmony with this theory.

It is not my intention to discuss the nature of the septic poison, but there can be little doubt, from the examinations which were made, that in the following cases it was microbic and not of a chemical nature.

Cases of sepsis of the newborn may be conveniently classified as follows:

First Group. *Cases of umbilical phlegmon which is a local sepsis, the poison entering the system from an umbilical sore, and being conveyed by the lymphatics.* —The New York Infant Asylum at Sixty-first Street and Tenth Avenue has, during the twenty-three years of its existence, been remarkably free from contagious and infectious diseases, but since September 1, 1887, seven cases, in which either local or systemic sepsis was diagnosticated, occurred in newborn infants in the Maternity Ward of this institution.

It is proper to state that at the same time diphtheria was epidemic in the asylum, and that five of the newborn infants had diphtheria, the pseudo-membrane appearing in its usual situation on the pharyngeal, nasal and laryngo-tracheal surfaces, and, in one or two of the patients, also lining the œsophagus. Moreover, two of the five infants with diphtheria had umbilical phlegmon of a few days' duration when the diphtheritic exudate appeared upon the faucial surface.

The question is, therefore, a proper one, whether in these two cases the phlegmons were a local manifestation of diphtheria, or whether the umbilical phlegmon and diphtheria were distinct diseases having a different microbic origin.

Case I.—Victor M. was born, after normal labor, on January 5, 1888, and the umbilicus was dressed with borated cotton. The mother did well and was able to leave her bed on the seventh or eighth day. Nothing unusual was noticed in the infant until January 11th, when a little suppuration was observed in the umbilical fossa, at or around the point of attachment of the cord, and on examination the walls of the umbilicus were found thickened and indurated. The appearance indicated the commencement of an umbilical phlegmon, and the skin covering it was red as in erysipelas. The phlegmon extended in area until January 14th, when the thickening and infiltration reached to the distance of about one and a half inches in every direction from the umbilicus, so that the form of the phlegmon was circular or wheel-shape. Its thickness or depth near the umbilicus was perhaps three-fourths of an inch, but near its margin the thickening and infiltration were less. The pulse on the 13th varied from 132 to 144, and the rectal temperature was 101.8°.

The case was carefully watched by Drs. Davis and Cook, the resident physicians, whose records I employ, and the faucial surface was daily inspected by them. On January 14th, the baby being nine days old, they observed for the first time the grayish-white exudate of diphtheria on each side of the fauces, and a day or two later also upon the Schneiderian surface, so closing the nostrils that respiration through them was impossible. The baby, on attempting to draw the nipple, became cyanotic, and was obliged to relinquish its hold. During the 14th and 15th the temperature fell to 98.5° and 98°, the pulse was very feeble and too rapid to be counted accurately, and the respiration varied from 24 to 48. Death occurred on the 15th, at the age of ten days.

The *autopsy* revealed a diphtheritic pseudo-membrane upon the faucial surface on both sides, extending downward, so as to cover both surfaces of the epiglottis, the entrance of the larynx and the laryngeal surface, completely concealing the vocal cords and the portion of the larynx above them.

[1] Read before the Pædiatric Section of the New York Academy of Medicine.

The trachea and bronchial tubes were free from the exudate. The lungs, in nearly every part, were thickly mottled with points of extravasated blood, and less abundant extravasations were observed in and upon other organs. The umbilical phlegmon removed entire, and in a frozen state from the intensity of the cold in the dead-house, was sent to the laboratory of the College of Physicians and Surgeons, where it was carefully examined by Dr. Prudden. He reports that the umbilical vessels were in their normal state, showing no evidence of disease, except the mouth of the umbilical vein, or that portion of the vein which was next to and in immediate relation with the umbilicus. Plugging the mouth of the vein and extending a few lines along the lumen of this vessel was a thrombus or blood-clot, from which Dr. Prudden was able to obtain cultures, and in the culture bed two forms of cocci were developed, to wit, the staphylococcus pyogenes aureus occurring in the usual form in groups, and the streptococcus pyogenes producing beautiful and delicate chains. The portion of the vein enclosing the thrombus or clot had preserved its integrity, so that the clot was entirely distinct from the phlegmon which covered the vein. It did not seem possible that microbes, ptomaines or elements of the blood could pass from one to the other, on account of the firm coats of the vein which were interposed between them.

Portions of the phlegmon placed in culture media developed the same forms of cocci as those produced from the clot that plugged the mouth of the vein. We infer that the cocci were the septic agents since no other cause of the sepsis was discovered, and that they were received from the umbilical sore. Some entered the thrombus and others, taken up by lymphatics, entered the tissues which surrounded the umbilicus, and gave rise to the phlegmonous inflammation.

It is easy to understand how microörganisms may enter the umbilical vein after the fall of the cord, when there may not be complete closure of the mouth of the vessel. But it can scarcely be doubted that in the above case as well as in cases which I am about to relate, the septic infection took place through the raw and denuded surface of the umbilical fossa, the lymphatics being the carriers of the poison. We know how frequently granulations sprout out from the umbilicus of the newborn, and wherever there is a surface denuded of cuticle from which these may arise, there is a surface from which microbes or toxic agents may be absorbed. The umbilicus, too, is a receptacle in which microbes conveyed in the floating dust of an apartment, in foul water used for bathing, in dirty sponges, or abdominal binders or umbilical dressings, would be likely to lodge. M. Bouchut, in his remarks on the fall of the umbilical cord, says, "cords voluminous, soft and plump, dry slowly and often suppurate at their base before they fall (Les cordons, volumineux, mous et gras, se dessèchent lentement et suppurent souvent à leur base avant de tomber)." (*Traité Pratique des Maladies des Nouveau-Nes*, etc.) With conditions so favorable for septic infection it is perhaps surprising that it does not more frequently occur, especially in hospital or asylum wards.

The patient whose case I have related evidently had systemic infection in addition to the local septic infection in the phlegmon. The numerous points of extravasated blood in the lungs and elsewhere showed this. But doubt must arise, whether this general infection occurred from the phlegmon in which there was intense hyperæmia and an active circulation as shown by the inflammatory redness of the cuticle, or whether it resulted from and was connected with the diphtheria. But we will relate cases of systemic infection in which there was no diphtheria and in which the septic agent or agents entered the system through the umbilicus.

The volume of the *Transactions of the London Pathological Society for 1879* contains an able and elaborate report of the committee appointed by that Society to investigate pyæmia, septicæmia and purulent infection. Their report is based on the examination of the records of 156 cases occurring in the London hospitals, and it throws light on the cause of hemorrhagic extravasations occurring in cases of septic infection of the system. They remark: "On microscopical examination of different organs, micrococci were found in all, or at least in some of the viscera. They were nearly all in the bloodvessels, completely plugging capillaries; in masses which sometimes produced varicosities, or even rupture of the vessels and extended into the contiguous tissues" (*Brit. Med. Journ.*, January 24, 1880).

CASE II.—Hilda M , born February 28, 1888, was plump and robust, weighing eight pounds and seven ounces. The mother appeared to be well until March 3d, when she had fever, and symptoms which were apparently due to pelvic cellulitis, probably of septic origin. The infant was fretful on March 3d and 4th, and on March 5th a small ulcer was observed in the umbilical fossa. The skin surrounding the umbilicus, over an area the size of a silver dollar, had a deep red color, and the tissues underneath, constituting the abdominal walls, were infiltrated and thickened. The phlegmon gradually extended in every direction from the umbilicus, so that, on March 6th, it nearly reached the ensiform cartilage above and the pelvis below. The fauces had been inspected daily, and at 5 P.M., March 6th, the grayish-white exudate of diphtheria was observed for the first time, covering the tonsillar portion of the fauces on each side. On March 7th the exudate had increased, the cry was hoarse, the fingers livid at times, and fluid regurgitated through the nostrils. The phlegmon occupied nearly the entire abdominal walls anteriorly. March 8th, surface cyanotic; respiration labored and at times accompanied by the expiratory moan; a diphtheritic pseudo-membrane in the right nostril. Death occurred at 6.30 A.M., March 9th, at the age of ten days, on the fourth or

fifth day of the phlegmon and on the third day of the diphtheritic exudate upon the fauces. The rectal temperature varied from 99.8° to 102.8°, until the last day, when it was subnormal, being 96.6°; the pulse varied from 90 to 112, and the respiration from 40 to 60. Both the pulse and respiration gradually increased in frequency until death, this increase being, probably, largely due to the double pneumonia. The tincture of the chloride of iron in glycerin, brandy and breast-milk were given internally; iodoform and carbolized oil applied to the umbilicus, and antiseptic sprays employed to the fauces and nostrils.

Prof. T. M Prudden kindly consented to conduct the autopsy, which was made with sterilized instruments and under conditions designed to prevent access to the body of adventitious germs. The following are his notes:

Autopsy.—The umbilical orifice was covered by a dry, brownish scab, beneath which was a small, rough-edged cavity, containing a yellowish, semi-solid mass. The abdominal wall, for about three centimetres around the umbilicus on all sides, was hard, thickened and dusky-red. A section through the abdominal wall in the line of the umbilicus showed that the wall was thickened to about 1.5 centimetres immediately around the latter.

Both the umbilical vein and the hypogastric arteries, for about 1.3 centimetres from their attachment to the abdominal wall, were much thickened, red and hard, and their inner layers were converted into a soft, yellowish, friable material. Beyond this point all of these vessels were filled with blood-clots and appeared normal. There was no peritonitis, and all of the abdominal organs were normal.

The heart was normal. The pharynx, larynx and trachea showed soft, reddish, friable patches of diphtheritic membrane, partially covering their free surfaces. This membrane did not extend into the bronchi. The lungs showed broncho-pneumonia in both lower lobes, with considerable consolidation.

The microscopical examination of the parts about the umbilicus showed that at the point of attachment of the cord was a small pus-cavity whose walls were infiltrated with small spheroidal cells, with a few rod-like bacteria, and with large numbers of spheroidal bacteria. Similar spheroidal bacteria were found in the purulent detritus contained in the cavity, as well as within the lumina and infiltrating the walls of the adjacent ends of the umbilical vein and the hypogastric arteries.

The tissues of the abdominal walls about the umbilicus were infiltrated with serum, fibrin and a moderate amount of pus. Spheroidal bacteria were rather scantily scattered in the lymph spaces of the swollen tissues, being most abundant near the umbilical vessels.

Biological examination of the contents of the inflamed portion of the umbilical vessel showed the presence of several species of bacteria. The species which was by far the most abundant was readily identified as the *staphylococcus pyogenes aureus.*

The anatomical diagnosis, then, is diphtheria of the pharynx, larynx and trachea, with double broncho-pneumonia, localized septic inflammation of the umbilical vein and hypogastric arteries, and of the abdominal wall surrounding them.

As the evidence of local infection is so great, it seemed desirable to gain some data as to the purity of the air in the wards. Accordingly, such analyses as time permitted were made by Dr. T. M. Cheeseman, Jr., who presented the following: "A biological examination of the air in the lying-in ward of the New York Infant Asylum, made on March 7, 1888, showed a very large number of living bacteria, of many different kinds. Among them the staphylococcus pyogenes aureus was of frequent occurrence. A second examination, made immediately after the usual sulphur disinfection, showed a large number of living germs."

Case III.—Janse J., born January 3, 1888, was wet-nursed by its mother, and apparently did well until January 16th, when the attention of the resident physician was directed to it and an umbilical phlegmon was discovered as large as a twenty-five cent piece, the skin covering it being intensely red; temperature 98.5°. The dressing, after the discovery of the phlegmon, consisted in dusting with iodoform and the application of carbolized oil (one part of carbolic acid to twenty-five of sweet oil). January 17th, phlegmon not extending and its surface less red. The redness, thickening and infiltration gradually abated, and on January 21st the patient was removed from quarantine. In this case there was no record of an umbilical sore; the fauces remained normal, so that the diagnosis of diphtheria was excluded. The mother continued well.

Case IV.—George C. was born in the maternity ward, January 14th. On January 25th the nurse observed a small vesicle upon the border of the umbilicus, and removed the cuticle covering it. Some hours afterward the attention of the resident physician, Dr. Davis, was called to it, who found thickening and infiltration of the umbilical wall, most marked on the side which had been occupied by the vesicle. The same treatment was employed as in Case III. The records of January 26th and 27th state that the redness and infiltration are abating, and on the 29th the umbilicus had returned to the normal state.

Case V.—John S., born October 14, 1887, the mother being a healthy primipara. The child was well developed at birth, weighing nine pounds and four ounces. The cord fell on the sixth day, and a small ulcer with indurated edges was observed in the umbilical fossa, at the point of attachment of the cord. The induration in and around the umbilicus increased slowly until the ninth day. On the ninth day the child was restless, and, on examination, the ulcer was found enlarged and surrounded by a zone of inflamed tissue half an inch in width. The inflammation, accompanied by the usual infiltration and swelling gradually extended, so that on the 15th the diameter of the inflamed area was two inches. The ulcer had also increased. On the twentieth day after birth the ulcer had attained the diameter of two inches and the depth of three-eighths of an inch, but the induration had begun to abate.

From this time improvement was progressive, and no notes were taken after the twenty-fourth day. The rectal temperature, ascertained each day from the ninth to the twenty-fourth day, varied from the normal to 102°. During the active period of the phlegmon it was usually from 100° to 101 5°, and the emaciation was progressive, the loss of weight being estimated at two pounds. The treatment consisted in dusting with iodoform and the use of a compress of absorbent cotton soaked with a solution of carbolic acid. During the second week, under the advice of the attending physician, Dr. George B. Fowler, calomel was also dusted on the sore. On the twenty-fourth day the infant was removed to the Post-Graduate School, and its subsequent history is unknown. The mother had no unfavorable symptom.

CASE VI.—Joseph D., born October 22, 1887; well-developed, weighing seven pounds thirteen ounces. The cord fell on the eighth day, leaving a small ulcer at its point of attachment with an indurated border. Two days later, the tenth day after birth, the ulcer had increased slightly being one-quarter of an inch in diameter. The surrounding tissues to the distance of one inch were thickened and indurated from inflammation. At no time was the temperature above 99.1°, and the child though restless, nursed well. The tumefaction and hardness surrounding the umbilicus remained about the same until the sixteenth day, after which they gradually abated. The ulcer had healed at the end of the fourth week. The mother on the third day after confinement had elevation of temperature which continued four days; and six weeks after the birth of the child she had diphtheria in the usual form. During the same month—October—twenty-seven obstetrical cases were under observation, but all except this patient convalesced without an unfavorable symptom.

SECOND GROUP.—*Cases in which the septic poison probably entered the system through the umbilical vein.*

CASE I.—In May, 1884, an infant died of sepsis at the New York Infant Asylum, at the age of fifteen days. It was apparently well until about the close of the first week, when the umbilicus was observed to be raw, and a slight oozing of a puriform liquid occurred from it. During the second week the abdomen was hard and tender, and peritonitis was diagnosticated. The cord fell on the seventh day. During the second week the abdomen was apparently painful; the temperature three days before death was 100.6° and two days before death 102.4°. Examination of the chest gave a negative result. The post-mortem examination was made by Dr. W. H. Welch, now Professor of Pathology in Johns Hopkins University. The abdomen contained six ounces of turbid serum with flakes of fibrin. The portion of the peritoneum covering the umbilical vein, and along the under surface of the liver, especially at the transverse fissure, was covered with fibrin, but the peritoneum generally did not exhibit any notable hyperæmic or inflammatory appearance. A number of lymphatic vessels filled with pus could be seen in the under surface of the diaphragm, showing in what way septic infection extends along the lymphatics. The lymphatics of the diaphragm open upon the pleural surface, and it is probable had the patient lived longer that septic pleuritis, perhaps on both sides, would have occurred. The umbilical vein was filled from the umbilicus to the transverse fissure of the liver with a grayish softened detritus, consisting of broken-down thrombi with a considerable proportion of pus. Softened thrombi could be traced the entire length of the umbilical vein, the walls of which were thickened and infiltrated from inflammation. No thrombi were seen in the portal vein or vena cava; the pericardium contained more than the normal amount of serum with flakes of fibrin; hemorrhagic points were observed in the posterior portions of the lungs under the endocardial surface, under the peritoneal coverings of the kidneys and mucous covering of their calices. The mother did well giving no evidence of disease of any kind.

CASE II.—This infant, born in the New York Infant Asylum, the date not being given, was well developed at birth, weighing eight pounds six ounces. When four or five days old it became feverish, the temperature rising to 104.6°. The cord separated at the usual time, and the umbilicus seemed healthy. At the age of two weeks an abscess appeared upon the scalp, another upon the back and another upon the nates, which raised the suspicion of septic poisoning. At the age of four weeks orchitis on one side occurred, which continued three weeks when it abated. When the child was two months old, a prominence appeared about half an inch above the umbilicus, which Dr. Parker, the resident physician, punctured, and bile flowed from the incision. Subsequently the incision closed, and bile flowed from the umbilicus and continued to flow until death, which occurred, in a state of much emaciation and weakness, at the age of eight months.

At the autopsy, made by Prof. Welch, remains of old abscesses were found upon the trunk and extremities, and an abscess holding four drachms of pus was found over the occipital bone. Underneath the abscess the bone was carious and the dura mater thickened. The umbilical vein was much larger than normal, its walls being infiltrated and thickened, and its lumen of about twice its usual diameter. It contained thickened bile. One of the branches of the vein, traced into the liver, opened into an abscess the size of a walnut, which contained thickened pus with bile. The abscess was in the right lobe near its posterior border. The mother remained well.

CASE III.—Lizzie C., born September 21, 1887, robust, weighing eight pounds, seemed well, taking the breast, and having normal evacuations until September 28th, when she became restless and refused the breast. Her temperature, rectal, was 101.4°, and her respiration was accelerated and accompanied by the expiratory moan. September 20th, temperature 103.6°, respiration accelerated and painful, and abdomen distended; no cough. The diagnosis of peritonitis, probably of septic

origin, was made, but the umbilicus was of usual appearance, and the desiccation and fall of the cord seemed normal. The elevation of temperature, even to 104.4°, the distention of abdomen and the hurried respiration with expiratory moan continued until death which occurred September 30th.

At the autopsy three ounces of sero-purulent liquid containing flakes of fibrin escaped from the peritoneal cavity. All the abdominal organs were covered by a fibrinous exudation, the intestines being matted together by it. The umbilical vein was pervious; it contained clots of blood and dirty-looking pus; but the umbilicus was apparently normal. A segment of the aortic valve was thickened and rigid, and attached to it was a fibrinous mass. The appearance indicated an endocarditis of slight extent. Under the microscope the walls of the umbilical vein presented their normal appearance; but its dirty-looking and disintegrating contents probably contained septic matter. The hepatic cells exhibited the peculiar cloudiness observed in parenchymatous inflammation. Otherwise the organs seemed healthy. In this case also the mother remained well.

Case IV.—A. B., born January 22, 1868, father healthy but mother strumous though in good health during her gestation. The infant born after an easy labor, was apparently well at birth, and it had sufficient breast milk. When it was thirteen days old, I was requested to visit it, as it had not been doing well, and I found it suffering from subcutaneous abscesses. Abscesses had occurred upon both legs, in the chest walls of the right mammary region, in and around the metatarso-phalangeal articulations of one foot and over both knee-joints. The child had fever, but its respiration was good until February 8th, when she suddenly had a severe attack of dyspnœa which continued until death, ten hours subsequently. On the following day Dr. Charles A. Leale and myself made the autopsy. The body was moderately emaciated. About one ounce of pus escaped from the right knee-joint. Pus was also found in the joint of the great toe on one side, and about two ounces in an abscess under the right pectoral muscle. A thin layer of tissue constituted the internal wall of the abscess, so that had life been prolonged a few days it would probably have broken through into the pleural cavity. The right lung was completely collapsed, and the pleura lining this lung, as well as that lining the thoracic walls on the same side, was covered by a fibrinous exudation. The left lung contained the normal, or perhaps more than normal, amount of air, so that it filled the pleural cavity, but there was a small amount of fibrinous exudate upon the parietal pleura in this cavity.

The trachea and lungs attached were removed, and on practising insufflation of these organs, air escaped from three openings in the posterior part of the right lung. These openings through which air had escaped into the pleural cavity causing collapse of the entire lung, were found on examination to have been produced by small abscesses in the tissue of the lung near its posterior surface. By the rupture of these abscesses, the pus which they contained escaped into the pleural cavity producing intense general pleuritis and pneumothorax. Numerous minute abscesses were found in both lungs, but only the three alluded to had been ruptured. It seemed certain that had the patient lived longer other abscesses would have ruptured.

Case V.—In the following case bacteria were found making their way along the umbilical vein at a distance from the umbilicus, and also in the tissues involved in the umbilical phlegmon. Those in the phlegmon were apparently derived from the umbilicus and conveyed by the lymphatics. This case, therefore, might be placed in the first group as well as the second.

Anne — was born in the New York Foundling Asylum on May 18, 1888. A few days after birth, and before the cord dropped, the umbilicus was observed to be foul from secretion or exudation in it, indicating a sore at the base of the fossa. On the seventh day an umbilical phlegmon was noticed small and confined to the umbilical walls. Three white patches were also observed on the roof of the palate near the velum, not raised and apparently not diphtheritic, resembling superficial ulcers. All the infants born in the Maternity Ward of the Foundling Asylum receive Credé's treatment, designed to prevent purulent conjunctivitis, one drop of a two per cent. solution of nitrate of silver being instilled between the eyelids of each eye. Although this child was thus treated, she had a pretty active purulent conjunctivitis of the left eye, to which our attention had now been called for the first time on the seventh day. Credé's treatment was immediately reapplied to this eye, one drop being introduced between the lids. This was followed by the corrosive sublimate treatment recommended by the late Prof. Samuel D. Gross. A solution of the sublimate, two grains to the ounce, was dropped between the lids every hour to two or three hours, four or five drops being used each time. The conjunctivitis rapidly abated, and in less than a week had nearly or quite disappeared. But the phlegmon presented a very angry appearance and the umbilical walls were greatly swollen, red and denuded of cuticle. The inflamed area had a diameter of about four inches with the umbilicus at the centre. Iodoform and carbolized oil were applied to the umbilicus and iron and stimulants given internally. The rectal temperature, taken May 26th, was 98°. Death occurred May 27th.

Autopsy, by Dr. W. P. Northrup, Curator, thirteen hours after death. Body well nourished; no rigor mortis; no external lesion, except the umbilical; the phlegmon definitely outlined and hard; its central half brown and dry; the infiltrated abdominal wall had twice its normal thickness; peritoneal surface of phlegmon congested and adherent to omentum; from this point to the transverse colon was a leash of dilated vessels, one inch in width and three or four inches in length; peritoneum injected and a few petechiæ observed in the parietal layer and the mesentery; mesentery deeply injected; liver and spleen normal; kidneys soft and flabby; points of hemorrhagic pneumonia in all the pulmonary lobes; abundant tenacious mucus covering the sur-

face of the stomach and intense injection, showing acute gastritis; cerebral pia mater finely injected, but without exudation; brain normal. Diagnosis, umbilical phlegmon, peritonitis, acute gastritis, hemorrhagic pneumonia.

Microscopical and biological examination by Prof. Prudden, at the laboratory of the College of Physicians and Surgeons. The small ragged cavity at the umbilicus contained a moderate amount of pus, cell detritus, and enormous numbers of bacteria of various forms, the spheroidal form predominating. The tissues of the abdominal wall about the umbilicus were infiltrated with fluid, fibrin and pus; scattered about in this exudation mass were small spheroidal bacteria. The hypogastric arteries and the umbilical vein were plugged with a clot for from one-half to three-quarters of an inch from their origin; their walls were greatly thickened by infiltration with inflammatory exudate. Both in the lumina of these vessels along the sides of the clot, and in the lymph spaces in their walls were enormous numbers of small spheroidal bacteria. These bacteria were present in the umbilical vein beyond the limits of the clot in the direction of the liver.

The *kidneys* showed moderate parenchymatous degeneration. The consolidated areas in the lungs are due to a nearly complete filling of the air spaces and the smaller bronchi with blood.

Cultures made from the inflamed tissue about the umbilicus and from the edges of the sloughing cavity, showed several species of bacteria common in the air and in the feces of children. In addition to these the staphylococcus pyogenes aureus was present in large numbers. A set of cultures from the inside of the umbilical vein, at a little distance from the sloughing cavity, revealed the presence of staphylococcus pyogenes aureus and streptococcus pyogenes, together with other forms. Cultures from the liver showed large numbers of staphylococcus pyogenes aureus, with considerable numbers of a stout bacillus similar to one abundant in the sloughing cavity. From the lung tissue, from the consolidated regions, enormous numbers of bacilli developed in a nearly pure culture, which corresponded in its biological characters to the bacterium lactis aërogenes of Escherich.

Remarks.—This child would thus seem to have been the victim of infection with the ordinary "suppurative bacteria" and with feces. We infer that fecal matter in some way came in contact with the umbilicus.

THIRD GROUP.—*It seems probable that in exceptional instances the septic poison in sepsis of the newborn is received in other ways or other channels than at the umbilicus.*

If sepsis of the new-born occur through absorption from an umbilical sore, may it not also from a sore located elsewhere? Decomposing and disintegrating animal tissue, wherever located, may be the source of septic infection. Moreover, medical literature contains histories of epidemics of puerperal fever, in which newborn infants perished with what was often designated erysipelas, but which the modern pathologist would unquestionably designate sepsis. The disease which I have described as umbilical phlegmon, a local sepsis, was commonly regarded by the older writers as a form of erysipelas. Dr. Condie, in his *Treatise on Diseases of Children*, described in the following lines what we would now designate sepsis:

"Erysipelas of infants very commonly occurs during the prevalence of epidemic puerperal fever. Children of mothers who become affected with the fever are often born with erysipelatous inflammation; others are attacked almost immediately after birth. Whether in these cases the disease is to be referred to a morbid matter applied to the skin in the womb, or to the same endemic or epidemic influence which gives rise to the disease of the parent it is difficult to say. According to M. Trousseau, infantile erysipelas is principally observed when puerperal fever prevails in the wards of the lying-in hospitals of Paris."

The late Dr. Folsom, of this city, furnished me the following sketch of cases which occurred in his practice and that of his partner: "About the year 1840, being then in practice in New Bedford, Mass., I was called to visit a man who complained of pain in the knee. The next morning he was easier, but the following evening his symptoms grew worse, and as I was engaged in a case of obstetrics, my partner, Dr. E. C., now dead, visited him. At my call, next morning, I unexpectedly found the patient dying. The disease was obscure, and at the autopsy next day no lesion was discovered. In making the examination, Dr. C. pricked his finger, and experiencing little inconvenience from it at first, he attended a case of confinement on the following morning. A few hours subsequently he was taken sick, and I took charge of the lady, who died in three days, having the tumid abdomen and symptoms of childbed fever. The infant of the patient was seized, when two days old, with erysipelas, appearing on the face and in spots on the trunk and limbs, and terminating fatally in one day. Dr. C.'s finger became swollen and painful, and the lymphatics of the forearm and arm became inflamed, presenting red lines, and the axillary glands suppurated. Though feverish and much prostrated, there was no appearance of erysipelas in his case. In about two weeks he resumed practice, and as at that time physicians in this country were not fully aware of the danger of communicating puerperal fever, he attended two, three, or four obstetrical cases each week, until the number reached fifteen. All the mothers died with symptoms of metro-peritonitis, and all the infants had erysipelas, commencing on the face or some part of the body, generally on the second or third day after birth, and in all terminating fatally within a week. This sad record was finally ended by the doctor's temporarily retiring from practice."

What better description could be given of a malignant form of septic infection? It will be observed that the unfortunate doctor did not have erysipelas but inflammation of the lymphatics, occurring from the poisoned finger, and the infant, who first contracted the disease and died of one day's sickness, exhibited red spots upon the trunk and limbs of an erysipelatous appearance. Did the doctor poison the mothers and infants at the same time by his digital examinations, did he poison the mothers by his infected fingers, and they in turn poison the babies through the placental circulation, or did the infected mothers communicate the poison through the breath or milk? This is an interesting subject

for inquiry in regard to which we are in the dark. Fortunately the profession are now fully aware of the danger of septic infection, so that no intelligent and prudent accoucheur would attend an obstetrical case after making a post-mortem examination, or visiting a case of puerperal fever, without change of clothing and thorough personal disinfection, and consequently cases belonging to our third group are much more rare than formerly.

It is evident that sepsis of the newborn might be prevented in a large proportion of instances by proper antiseptic dressing of the navel. Boric acid is a feeble and inefficient antiseptic, and the borated cotton which was employed in dressing the navel when the cases in the maternity ward, which have been related above, occurred, was inadequate to prevent infection. Of the powders which might be employed for this purpose salicylic acid or deodorized iodoform mixed with starch would appear to be much more efficient. Credé's method of preventing purulent conjunctivitis by instilling one drop of a two per cent. solution of nitrate of silver between the lids has been very effectual. Probably in a similar manner umbilical phlegmon might be prevented in maternity wards by bathing daily the umbilicus with a solution of the sublimate, grs. ij to the pint.

When an umbilical phlegmon has commenced, we have employed dusting with iodoform, the application to navel, every two hours, of carbolized sweet oil (1 to 30), and bathing the navel with a solution of corrosive sublimate, two grains to the pint of distilled or boiled water. In some of the cases thus treated when the phlegmons were small the patients gradually recovered, but in most of the cases the phlegmons were so large, and the microbes at such a distance from the umbilicus in the tissue of the abdominal wall that antiseptics applied upon and around the umbilicus were not curative. Newborn infants are probably too young and feeble to be satisfactorily treated by incisions in the phlegmon and the application of antiseptics to the incised surfaces, else this treatment might be more efficient than treatment without such incisions.

DIPHTHERIA OF THE NEWBORN.

Diphtheria of the newborn is rare, and the literature of it meagre. Nevertheless, a considerable number of cases under the age of one month have been reported. Oertel is mistaken when he writes "... in the first half year the infant organism seems to be not at all susceptible to the disease." Dr. Abram Jacobi writes in his *Treatise on Diphtheria*, "I have met three cases of diphtheria of the larynx and pharynx in the newly born myself. One of these became sick on the ninth day after birth and died on the thirteenth day; the other died on the sixteenth day after birth; the third was taken when seven days old and died on the ninth day." Dr. Jacobi alludes to the thesis of Siréday, of Paris, published in 1877, in which eighteen cases of diphtheria of the newborn are related. They occurred during the spring of 1877 in the hospital Lariboisière. He alludes also to several cases reported by Parrot, one of fifteen days by Bretonneau, one of seventeen days by Bednar, one of eight days by Bouchut and one of seven days by Weikert.

Diphtheria, which had been prevailing in the New York Infant Asylum since October, 1887, appeared in the maternity wards of the institution in January, 1888. The patients affected with it were all newborn infants, the mothers, although mostly young, escaping.

Case I.—Violet M., whose case is related in the paper on sepsis. When she was six days old the phlegmon commenced; two days afterward nasal catarrh began and a day later when she was nine days old the diphtheritic exudate was observed in her left nostril and upon the faucial surface. The symptoms in full are recorded in the paper on sepsis. Death occurred at the age of ten days. At the autopsy the pseudo-membrane was found on the surface of the fauces, both surfaces of the epiglottis and the entire larynx to a point a little below the vocal cords. The vocal cords were completely concealed from view by the exudate.

Case II.—Olivia G., born January 8th, was wet-nursed by her mother, and was apparently well until January 14th, when she became restless. On the following day, when she was seven days old, she was carefully examined and diphtheritic patches were observed upon the faucial surface. Rectal temperature 100°, respiration 36, pulse 120. She had commencing nasal catarrh, which so obstructed the breathing that she could not take the breast, and she was fed with the mother's milk from a spoon. Directions were given to syringe the nostrils at intervals of two hours with the following:

R.—Ol. eucalypti	℥j.
Sodii bicarbonat.	āā ʒij.
Sodii benzoat.	
Glycerinæ	ʒj.
Aq. calcis	℥vj.—M.

Small doses of the tincture of the chloride of iron and brandy were also given at short intervals.

16th. Deglutition is so difficult that almost no nutriment is taken; breathing obstructed; features and extremities livid; temperature 101⅕° to 103⅕°; pulse 120, 112, 104; respiration 32, 34, 46; discharge from nares tinged with blood. The mustard bath was employed, but without producing reaction.

17th. The diphtheritic patches remain on the faucial surface, and the right nostril is plugged by an exudate of the same appearance. Rectal temperature at different hours through the day was 98½°, 98°, 99°, 98°; pulse 120, 118; respiration 32, 38; pulse weak, and surface cyanotic and cool. About one teaspoonful of brandy was given through the day, and the same quantity of milk; hot bottles applied.

18th. Nostrils discharging freely; temperature 103°; pulse 140; respiration 45, 60. Cry hoarse; pulse very feeble. Died at 11 P.M.

Autopsy.—January 19th. In addition to the diphtheritic exudation, already mentioned, occurring upon the faucial and nasal surfaces, a pseudo-membrane was found covering the larynx, trachea and œsophagus to within one inch of the stomach. The lungs contained numerous points of extravasated blood. No notable change was observed in the appearance of the kidneys, heart and other organs.

CASE III.—Victor K., born December 7, 1887. On January 13th, when Victor was thirty-seven days old, his mother called the attention of the resident physician to him as he seemed seriously sick. His temperature was 103.2°, and his breathing indicated nasal catarrh. On the following day, the 14th, the characteristic grayish-white exudation of diphtheria was observed on the left side of the uvula. The inability to remove it by brush or washing demonstrated its diphtheritic nature. The temperature on the 14th varied from 99° to 102.4°; the pulse from 88 to 96; and the respiration from 26 to 38, having the Cheyne-Stoke's character. The pulse was weak and the extremities and face cyanotic. On the 15th his temperature was 102°; respiration 20 with long intervals; and the frequency of the pulse could not be ascertained from the weak action of the heart. Death occurred at 5 P.M. Diagnosis bronchitis, nasal and slight pharyngeal diphtheria. The right cavities of the heart were greatly distended with blood. No pseudo-membrane was found in the larynx, trachea and bronchial tubes but only the hyperæmia of bronchitis. Lungs normal, except hypostatic congestion of posterior portion of each.

CASE IV.—Vincent B., born December 31, 1887, was apparently well until January 17th, when symptoms of a catarrhal nature attracted attention. The nostrils seemed to be unaffected, but upon the posterior surface of the pharynx was a distinct diphtheritic patch; temperature 98.5°; respiration 32 to 40; pulse 114 to 120.

18th. Discharge from nostrils; temperature 98.5°; pulse 116 to 118; respiration 36. The same nasal and throat wash was used as in the other case. On the 19th the exudate on the surface of the fauces had nearly or quite disappeared.

20th. Nasal catarrh less, and infant apparently improving. Pulse 118; respiration 28; temperature 98.5°.

21st. No discharge from nostrils and fauces apparently free from pseudo-membrane. The infant soon fully recovered.

CASE V.—Hilda M. This case is fully detailed in the article on "Sepsis." She was fretful when four days old, and at the age of six days an umbilical phlegmon was discovered. The fauces were inspected daily, and when she was seven days old the grayish-white exudate of diphtheria was observed for the first time covering both tonsils. On the following day the exudate appeared in the right nostril. Death occurred on the tenth day, and at the autopsy in addition to the phlegmon, the pharynx, larynx and trachea showed soft, reddish, friable patches of diphtheritic pseudo-membrane partially covering their surfaces. The membrane did not extend into the bronchi.

Diphtheria of the newborn is sometimes wrongly diagnosticated. Thus in the New York Foundling Asylum where diphtheria was occurring, the tonsils of an infant a few days after birth presented a grayish-white appearance, and diphtheria was diagnosticated. After its death the curator, Dr. Northrup, discovered a pultaceous state of the surface of the tonsils, but no pseudo-membrane. The disease was not diphtheria. But in regard to the cases related above there can be no doubt of the correctness of the diagnosis, unless in regard to Case III. The occurrence of five cases in so short a time, in a rather small maternity service, shows that under certain circumstances the newborn infant exhibits considerable susceptibility to diphtheria.

A very interesting and important subject for consideration arises in connection with these cases, to wit, personal and domiciliary disinfection. The occurrence of so many cases of umbilical phlegmon and diphtheria showed that the maternity ward was infected to such a degree that subsequent patients could not be safely admitted without thorough disinfection. The ward was vacated, the windows, doors and crevices closed, and forty pounds of sulphur, or two pounds to the one hundred cubic feet of air, were burnt during the day until it was consumed. After some hours the windows and doors were opened, and Drs. Prudden and Cheeseman immediately raised a dust from the floor and bedding and allowed it to settle in culture media. All other sources of infection were excluded from the media. The culture produced so large a number of microbes that they overlaid each other, but they were able to distinguish the streptococcus pyogenes which had been previously discovered in the umbilical phlegmon. Although more sulphur was employed than is recommended by the Health Board, the result appears to have been negative as regards destruction of the microbes. Some more efficient mode of domiciliary infection should be devised. I recommend to wash the floors, walls and furniture of an infected room with a strong solution of corrosive sublimate. This might be done frequently during the progress of a case of diphtheria. In order to disinfect the air of an apartment where a diphtheritic patient is under treatment, a disfectant mixture should be placed over the gas, oil or other stove in shallow pans with broad surfaces, and kept in a state of constant ebulition or simmering. I prefer for this purpose the following prescription:

R.—Acidi carbolici . . . . . ℥j.
Ol. eucalypti . . . . . ℥ss.
Spts. terebinth. . . . . ℥vj.—M.

Add one tablespoonful to one quart of water.

One important advantage arises, I think, from this

mode of disinfecting the air, namely, that the physician and attendants are less likely to convey the disease in their clothing. It is probable that the danger of communicating diphtheria to other children, or to obstetrical cases is greatly diminished if the air be sufficiently loaded with the disinfecting vapor. No more cases have occurred in the Infant Asylum since this mode of disinfection was employed.

Although the prognosis in diphtheria of the newborn is very bad, it is not necessarily fatal as is seen by the above cases. Does it require, on account of the age, any modification of the usual mode of treatment? Very few, probably, would recommend the internal use of corrosive sublimate for patients so young, but there seems no objection to its local use by the swab or camel-hair pencil of so weak a solution as that employed by Dr. Oatman and others, two grains to the pint of water. The old remedy of the tincture of the chloride of iron, so long employed as a blood-restorer, and properly employed as a chief remedy in diphtheria, which is attended by a rapid destruction of the red corpuscles and progressive anæmia, seems to be a proper remedy for any age. It was employed in the above cases in frequent doses of one to two drops.

As the ordinary mode of domiciliary disinfection seemed to be entirely futile in the maternity wards where the above cases occurred, it seemed to me advisable to obtain the views of so eminent an authority as Dr. E. R. Squibb, of Brooklyn, and he has kindly favored me with the following note:

Remarks by E. R. Squibb, M.D.—Within the past ten years the efficacy of sulphur fumigation against infectious material has been repeatedly denied and reaffirmed upon very good authority, and observations, apparently made with accuracy and care, have been reported from time to time, to prove both sides of the question; so that all that can now be said is that burning sulphur is of doubtful efficacy, with the weight of the highest authorities in bacteriology against it. But to this it must be added that it is still largely used by very intelligent bodies in large institutions, boards of health, etc., where it would not be likely long to maintain an unearned confidence.

How often the fumes are applied dry, and how often moist, no one can tell from the current record; and how many of the failures of the dry gas would be successes in the presence of moisture there is no means of knowing.

Formerly, when sulphur was burned in closed chambers as a disinfectant, the surfaces were all wetted, and the pot of burning sulphur was set in water or in wet sand, that the heat might evaporate off a constant supply of watery vapor.

These conditions are now frequently, if not generally, neglected, and where this is the case failure on principle should be the rule.

Nearly all, if not all, chemical disinfectants are in a state of tension, ready to change on coming in contact with the matter to which they are applicable, and these changes are either by oxidation or deoxidation, and the moment of greatest power or activity is the moment of change, where they, by reacting with infectious matter, pass from a state of tension to a state of rest under new relations. The agency through which these changes almost universally become operative is the vapor of water.

When sulphur is burned in a close chamber, the dioxide is formed by condensing two molecules of oxygen from the air upon each molecule of the sulphur, and a heavy gas is the result, which tends to settle at the bottom of the chamber, and to run out through the lower cracks. Any moisture present is at once seized by this rather inactive anhydride, first forming sulphurous acid, and then, by oxidation from the air, sulphuric acid. The dry gas, or anhydride, not only seizes with avidity all watery vapor in the air, but also the water held in the surfaces of all bodies with which it comes in contact, and in the presence of this moisture only is it ready for further oxidation. Then it is by this oxidation that it deoxidizes the matters with which it is in moist contact, filling the surfaces of these matters first with sulphurous acid, then, by the change, with sulphuric acid; and it is during these changes that its power is exerted.

If there be no moisture supplied to the burning sulphur, that which was present in the air and the surfaces of the chamber is soon used up, and the dry gas remains indefinitely in a comparatively inactive, ineffective condition. The dry, passive anhydride would necessarily destroy all organisms which breathed in any degree, because breathing surfaces are moist. But in embryonic life, protected by shell, as in seed, if the shell be dry the gas would be impotent. Many bacteriologists have admitted that burning sulphur would kill bacteria, but not germs.

ACUTE INFECTIOUS PHARYNGITIS.

By E. M. Hewish, M.D., F.R.C.S. Eng.,
of Philadelphia.

The above-described disease will, I believe, to the majority of us, prove to be a new one. How many may have anticipated the addition of a new medical term to our nomenclature, to express a pathological condition with which they, at one time or another, may have met, it is impossible to say, since we have not in medical literature probably more than a half dozen cases. What impressed upon me the novelty, and later on the extreme gravity of the disease, was having met with a case in practice during March last.

While in attendance upon another member of this gentleman's family he casually drew my attention to

his throat, which he said was painful on swallowing. On examining it, I found the anterior pillars, uvula, tonsils and posterior pillars of the fauces congested. The patient complained of lassitude, vague pains in the extremities, voice not clear and a considerable amount of tenacious mucus; it requiring great effort to free the throat. The patient, a man of forty-two years, weight about 180 pounds, had always been in good health. Temp. 101° F., pulse 90. Prescribed tab. hydrochlor. cocaine gr. one-fifth, every hour, to relieve dysphagia, also gargle ammon. mur. gr. v. to ʒss water, and a pill of

R.—Quin. sulph. . . . . gr. ij.
Ammon. mur. . . . gr. ij.
Sol. ferri chlor. . . . gr. ij.
One after each meal.

Patient continued to attend to his business (merchant tailor), contrary to monitions, and it being the severe weather of last March, matters were readily precipitated.

In three days' time he took to bed, as advised, and since the articular stiffness was still complained of, I prescribed R. sod. salicyl. gr. xv every three hours till relieved, but little relief was obtained.

At this time, cervical tumefaction began to show itself; no special glands could be felt enlarged; the swelling was symmetrical in all directions; dysphagia severe; tonsils much enlarged and, on palpation were quite hard, showing no tendency to formation of abscess; nor did they at any time during the disease; voice husky, and dyspnœa somewhat complained of.

5th day. Saw patient early, as he complained severely of dyspnœa and dysphagia; temp. 102°, pulse 110; had no rest during the night on account of inability to remain in bed, and consequently sat up in a chair. Tonsils and uvula same as heretofore; a small ulcer had formed on the side of the uvula. Externally the swelling had increased.

6th day. Saw patient early, as dyspnœa was very alarming to himself and family, who thought he must soon strangle if not relieved. He sat up during the night, although I had ordered him ¼ gr. morph. sulph. and had it repeated in an hour, but it did not secure rest. Little nourishment was taken on account of dysphagia. Neck very much swollen, but no fluctuation or tenderness. Lungs showed no symptoms of complication; heart-sounds normal; temp. 101° F.; pulse 112. Patient now taking tr. ferri mur., ♏ x, ammon. mur., gr. v. aquæ, ʒss, every two hours.

7th day. Dyspnœa still more marked. Dr. W. Osler saw the case with me this A. M. Same treatment continued as heretofore. We anticipated tracheotomy, should breathing not improve. Was with patient most of the day. Toward evening the eyelids grew quite puffy. Dyspnœa increasing.

8th day. Summoned early to see patient, as his family thought he could not breathe much longer, with the same difficulty. With Dr. W. Ker Shea's assistance I opened the larynx without an anæsthetic. We had promised considerable relief for the dyspnœa from the operation, but to our extreme annoyance the amount of relief which we had anticipated was not forthcoming.

Drs. W. Osler and H. R. Wharton saw the patient with me again to-day. Although the tube which we used was a large one, Dr. Wharton thought that his largest and longest canula might give more relief; it was introduced, but the dyspnœa still increased.

9th day. At 6 A. M. patient died.

Professor Senator (*Berliner klin. Wochenschrift*) discusses the pathology of this disease, and I do not think we can do better than give his own words:

The term infectious pharyngitis, which should be supplemented by the word "primary," is used to indicate a rare and "perhaps always fatal" form of pharyngitis, not hitherto described in text-books of medicine. Two examples had occurred within the last few months, and a study of similar cases had revealed three more as having occurred within the last twelve years. In all these cases, reported at a meeting of the Berlin Medical Society on January 4th and discussed on January 18th, the disease affected previously healthy persons, without any apparent cause, and ran an acute course, ending in death in a few days. It began with cervical pains and dysphagia, accompanied by fever, often moderate, then followed by hoarseness or loss of voice and dyspnœa; finally, the sensorium was affected, and death quickly ensued.

The chief anatomical sign, found post-mortem, was diffuse purulent infiltration of the deeper tissues of the pharyngeal mucous membrane, the inflammation extending to the trachea and glands of the neck and, secondarily, to other parts, especially the gastric mucous membrane. Senator is of the opinion that many cases hitherto regarded as examples of acute œdema of the larynx were in reality cases of the above disease. Notably, in a case of Cruveilhier's, the pharynx was affected for a day or two before the larynx. The very rare "typical œdematous laryngitis," mentioned by Sir Morell Mackenzie as of septic origin, is also claimed as in all probability affording an example of the disease in question.

The spleen was generally enlarged in Senator's cases, and the kidneys, as a rule, showed parenchymatous inflammation. A peculiar exanthem appeared in one case.

The blood removed both before and after death had been carefully examined, but no specific microorganisms had revealed themselves in attempted cultivations; injections of which, as also those of fresh blood, had been harmless in rabbits. The streptococcus of Friedländer (erysipelas coccus) was certainly absent.

In the discussion which followed, Dr. Guttman argued that the cases were probably erysipelatous, in spite of the fact just mentioned, and referred to Ziemssen's *Special Pathology* and Eichhorst's *Pathology*.

Virchow leaned to Guttman's opinion, but also described other pharyngeal diseases which might mislead, especially metastatic abscesses in puerperal fever, suppurative pharyngitis accompanying acute gastritis and, in one case, mediastinitis; but Senator urged, in his reply, that there was no abscess in any of his cases, but a diffuse purulent infiltration, always beginning in the pharynx. The cause was absolutely unknown to him at present, but the system was very rapidly affected in a characteristic manner, and tracheotomy was of no avail. He had no doubt that a study of the subject, as revealed in hospital records, would disclose numerous examples of this disease, overlooked under the title of "acute œdema of the larynx."

Unfortunately we could not obtain a post-mortem examination in our case.

SULPHONAL.

By LUTHER LEE JOHNSON, M.D.,
of Garretsville, Ohio.

The literature regarding this new drug is extremely meagre. My experience with it is limited to its action upon one patient.

Mr. S., æt. forty-nine years, a lawyer, had suffered from insomnia for twenty years; as his legal business increased his trouble, he had to abandon his profession, and for years he has been existing on from one to three hours of sleep out of every twenty-four. He has been under skilled treatment and is as well informed regarding the physiological action of narcotics and hypnotics as the average practitioner of medicine. He had finally adopted the use of from one to two ounces of alcohol just before retiring for the night; this would produce from one to three hours of stupor (not sleep), and he had reached a point where suicide was contemplated.

I saw a notice of the new hypnotic in The Medical News, and, after some trouble, I obtained one ounce of the drug. I gave my patient twenty grains dissolved in very warm water; he became drowsy in fifteen minutes and retired, getting eight hours of quiet, peaceful sleep. This was six weeks ago, and Mr. S. is now a new man. He has resumed labor, and gets, every night, from seven to eight hours of refreshing sleep, notwithstanding the fact that the dose has been reduced to fifteen grains.

The patient has been watched closely, and I cannot see any injurious effects from the use of the drug.

He took thirty grains one evening and slept nine hours, and was very sleepy the next forenoon as a result of the increased dose. I think, by taking the drug for a time and gradually lessening the dose, the normal tendency to sleep will be reëstablished and my patient cured.

The drug costs four dollars per ounce. I find it soluble in twenty to thirty parts of very warm water; not so in cold water or alcohol. When dissolved it develops a bitter taste. I hope to hear from the profession regarding this new remedy, as I think it has a great future.

MEDICAL PROGRESS.

The Treatment of Traumatic Tetanus with Hydrobromate of Conine.—Demme, (xxiv. Report of the Jenner Children's Hospital at Rome), after having relieved a case of rheumatic tetanus by means of hydrobromate of conine, was led to try the remedy in a case of traumatic variety. Fourteen days before admission, a robust boy had received a lacerated wound upon the right index finger from a saw. There was malaise on the second day; on the seventh, there was extension of the muscles of the extremities, trismus, opisthotonos; the intelligence was clear; pulse, 100; temperature normal; respiration 24. One twenty-fifth of a grain of hydrobromate of conine were immediately injected every two hours, with the result that the attacks generally became less frequent and decidedly shorter. The patient was again able to sleep and to swallow. There was profuse secretion of sweat and saliva. After the patient had received nineteen grains of conine in forty-eight hours, severe attacks of suffocation occurred, necessitating the withdrawal of the drug and the institution of artificial respiration. At times, there were signs of collapse. In the course of the next three days, during which chloral hydrate was given instead of conine, the tetanic attacks again became more frequent, while occasional manifestations of paralysis of the diaphragm and of the intercostal muscles simultaneously appeared. Besides, certain spots of pneumonic consolidation, present on admission, progressed. Death occurred on the fourth day. The autopsy revealed inhalation pneumonia (Schluckpneumonie) of both lungs, probably existing prior to admission. Notwithstanding the unfavorable termination, the author recommends conine for further, carefully conducted experiments, as he maintains that probably after further new experience recovery may be attained in cases of a less acute character.—*Medicin. Chirurg. Rundschau*, August 1, 1888.

Substitute for Cod-liver Oil.—The following combination is highly recommended by Lamande for delicate stomachs which refuse cod-liver oil:

R.—Glycerin	. . . . .	℥x.
Tinct. iodi.	. . . .	℥ss.
Potass. iodidi	. . . .	grs. xij.—M.

Sig. A teaspoonful fifteen minutes before meals.—*Gazette Médicale*, August, 1888.

Test for Liver Diseases by the Saliva.—Fenwick, of London, gives his method of procedure as follows: "A solution of sulphocyanide of iron was prepared of definite strength, and was graduated by successive dilutions, so that each was only three-quarters of that above it. These were placed in the small flat bottles used by spec-

troscopists, each bottle being of equal thickness. He took his own saliva, which agreed in color with that formerly taken as normal (which was obtained by mixing the salivas of a number of healthy people together) as the normal standard, and the bottles were labelled + or —, according as they differed from it. Each of the salivas, when examined, was mixed with a definite quantity of the tincture of the perchloride of iron, filtered through cotton-wool and being placed in a spectroscopic bottle of equal thickness was carefully compared with the graduated strengths of the sulphocyanide of iron."

Five hundred patients in the hospital wards were thus examined, week by week, besides a large number of others who were subjected to a less rigid examination.

The results, to say the least, are very interesting. We have only space to refer to those obtained from thirteen cases of typhoid. In these, during the second week previous to convalescence (*i. e.*, the date at which the normal temperature was first permanently resumed) the amount of sulphocyanide was + ¾ (as the saliva was at this time in very small quantity, the total amount of the test present must have been very small), in the succeeding week it rose to + 2; in the first week after convalescence to + 2¾; in the second week to + 3¼; in the third to + 3¾; in the fourth to + 3; and remained high till after the seventh week of convalescence, in some instances rising to + 7. Another point of interest lies in the fact that where the duration of the febrile stage was short the increase of the salivary salt was less abrupt, but the duration of the convalescence, as shown by the increase of salt, was longer. Hence the amount of the salt secreted during the first week of convalescence should help us greatly in our attempts to foretell the length of this, and prove, therefore, a fact of high value. But we cannot help remarking that the statement that typhoid with a febrile stage of less than twenty-one days has a longer convalescence than the same disease when the fever exceeds twenty-one days is a very hard saying in the ears of any practical physician.—*Birmingham Medical Review*, August, 1888.

Tubercular Meningitis.—M. Lemoine, in the *Revue Special de l'Antiseptics*, speaks highly of the internal administration of iodoform in this disease, and urges its employment from the beginning of the attack. He has given as much as eight grains daily, for a period of three months, with the happiest results, no toxic effects being noted. It is administered in capsules, and he thinks the addition of a little ether of advantage in aiding its absorption.

Œdema from Antipyrin.—Grognot relates the case of a patient who took fifteen grains of antipyrin and in twenty minutes experienced marked dryness of the throat and nasal passages and great dyspnœa. The voice became husky and the face rapidly grew œdematous and pale. The œdema was especially noticeable about the lower jaw and under the eyes. These symptoms disappeared in half an hour, but returned on another occasion when antipyrin was again administered.—*Bulletin General Therapeutique*, August, 1888.

Smokers' Vertigo.—Decaisne, in an address before the Paris Academy of Medicine (*Deutsche med. Ztg.*, No. 51, 1888), ascribed the vertigo to which smokers are prone, to the contraction of the cerebral vessels, as it has been experimentally shown that nicotine stimulates the muscular layer of the vessels. The patient has a sensation of emptiness, a feeling as if he were about to lose consciousness. He makes the greatest effort to recover himself, but fails to do so. His movements are incoördinate and the senses receive the most deceptive impressions. Everything seems to revolve about the patient, and when he closes his eyes, his body seems to participate in this movement.

Decaisne thus summarizes the results of his twenty-five years' experience: 1. Of sixty-three persons from twenty-nine to sixty-six years of age, forty-nine or fifty were sixty-six years old. 2. More than half manifested, besides the vertigo, digestive disorders, alternate constipation and diarrhœa, dyspnœa, increased uninary secretion, sleeplessness and palpitations; a third showed intermittent pulse and angina granulosa; some emphysema, aphtha, amblyopia and bloody expectoration. 3. Thirty-seven observations refer to smoking upon an empty stomach; in these the vertigo almost always appeared in the morning. 4. In one-third of the cases, the occurrence of the vertigo was associated with suppression of the perspiration and marked diminution of the urinary secretion. 5. The symptoms of smokers' vertigo were several times confounded with those of cerebral congestion and even with those of cardiac disease. The symptoms of congestion are explained by the contraction of the vessels giving way to relaxation. 6. The general treatment consists in the absolute withdrawal of tobacco and, in some cases, in the regulation of the mode of living. To this Decaisne usually adds laxatives, warm baths, magnesia and bitter tonics. On twenty-eight occasions, in the progress of the attack, he has made subcutaneous injections of ether, which overcame the vertigo in six or seven minutes. Seven of thirty-nine persons who smoked on an empty stomach, thirty-three had the vertigo disappear immediately upon smoking only after taking food. —*Medicin. Chirurg. Rundschau*, August 1, 1888.

Creolin in Purulent Ophthalmia and Gonorrhœa.—Acute and chronic purulent ophthalmia is satisfactorily treated, according to Dr. Margaritti, by means of a solution of creolin of the strength of 1 in 400. This is instilled into the eyes and used for moistening compresses which are applied externally. At first a burning sensation is experienced, but after about five minutes this subsides and the eyes feel much more easy, and the patient is able to open them without difficulty. Gonorrhœa which has resisted other treatment has frequently yielded in Dr. Margaritti's practice to irrigations, twice daily, with a solution of creolin of the strength of 5 to 8 per cent., administered through a hollow sound.—*Lancet*, August 18, 1888.

Cocaine in Ophthalmic Surgery.—There have been published a number of cases of corneal opacity following upon cataract operation in which cocaine had been used. Wicherkuwicz (*Allg. Wiener. med. Ztg.*, No. 1, 1888) ascribes the complication to the too liberal use of strong solutions; he, therefore, applies a three to five per cent. solution but twice shortly before the operation and has since met with no opacities. Cocaine diminishes the intraocular pressure, and the frequent instillation may, after the operation, induce such a diminution that the

margins of the wound do not approximate, in consequence of which the nutrition of the cornea suffers, as evidenced subsequently by an opacity of the parenchyma. For the same reason he makes incisions and performs iridectomies without cocaine, or he confines himself to a single instillation of a weak solution. The author recommends the subcutaneous use of cocaine in the removal of small swellings, in ectropion, ptosis and trichiasis operations, etc. He makes, antiseptically, four punctures in the region of the area of operation, and employs half a syringeful of a three to five per cent. solution, the needle being introduced obliquely and to a sufficient depth beneath the skin. As the anæsthesia from subcutaneous injection occurs later than that from the local use, it is advisable to make the injection ten to fifteen minutes before the operation.—*Medicin. Chirurg. Rundschau*, August 1; from *Breslauer ärztl. Zeitschr.*, No. 11, 1888.

Vapor of Ipecacuanha Wine in Bronchitis.—According to Morrell, of London, great benefit is derived in chronic bronchitis from the inhalation of the vapor of wine of ipecacuanha. He has used it in fibroid phthisis and obtained great amelioration, even when no constitutional means were employed. The vapor should be inhaled when hot and the patient kept in a warm room for some time after. It may be used for ten minutes at a time, three or four times a day. In hoarseness, due to acute congestion of the vocal cords, it is especially serviceable. —*L'Union Médicale.*

Accidents caused by the Exploring Needle.—Dr. Biggs, of New York, draws especial attention to the fact that the exploring needle is not a harmless instrument. He mentioned cases of pneumo-thorax caused by it, some of which were fatal, and draws the following conclusions:

1. The employment of the exploring needle is not infrequently attended by considerable danger, and a number of deaths have directly resulted from its use.

2. The indiscriminate, careless and routine resort to exploration with a needle should be condemned. This procedure should not be resorted to without careful consideration of the conditions obtaining in each case and the results that may follow the puncture. The site for the puncture should be thoughtfully chosen, the puncture carefully made with complete antiseptic precautions and the smallest needle that will answer the purpose employed.

3. The puncture of collections of fluids with tense walls in relation with serous surfaces should be, as far as possible, avoided, and, if it is resorted to, sufficient fluid should be withdrawn to relieve the tension upon the walls of the sac. In many cases certainly an exploratory operation would be attended by less danger.

4. In the introduction of the needle into deeply seated infectious matter the nature of the intervening tissue should be carefully considered.

5. The needle before use should be always thoroughly disinfected, preferably by heating in the flame of an alcohol lamp or a Bunsen burner.

6. The skin where the puncture is to be made should be rendered thoroughly aseptic by first scrubbing with soap and water and then washing with an antiseptic solution.

7. The dangers attending the use of this valuable adjuvant in diagnosis should not in the slightest interfere with its employment in properly selected cases, where due precautions are observed as to its use.—*New York Medical Journal*, August 18, 1888.

Effect of Nicotine on the Female Generative Organs.—Recent investigations in Paris tend to show that the women working in tobacco factories are considerably affected by the nicotine. Those becoming pregnant habitually abort and the menstrual periods are very irregular. Nicotine, being a motor-excitant, has a direct action on the uterine walls.—*Journal de Médecine*, Aug. 1888.

The Technique and the Value of Mucous Membrane Transplantation.—Wölfler (*Congress of Surgery*, xvii.) states that his method of repairing deficiencies of the mucous membrane, after the removal of cicatrices, is of equal importance to Thiersch's method of skin grafting, in the healing of wounds of the cutaneous surface. By this means, it has become possible on a more extensive scale than heretofore, to remove cicatrices from the mucous membrane of the œsophagus, of the buccal cavity, of the rectum, of the urethra, etc. The author applied grafts in a manner similar to that followed in skin grafting, obtaining his tissue, however, from the mucous membrane of prolapsus uteri, prolapsus recti, etc.; later on, he used the mucous membrane of the frog's stomach, of the rabbit's bladder, etc.; these proved entirely efficient. In this way the author was enabled, in three cases of impassable stricture of the urethra, after excision of the obstructing stricture, to create a new mucous membrane. He also used this method, with good results, in two cases of blepharoplasty, in one case each of rhino- and meloplasty. Thiersch commends this measure as a most important advance.—*Medicin. Chirurg. Rundschau*, August 1.

Treatment of Leukæmia.—The *Zeitschrift f. klin. Medicin.*, Band XL., Heft 122, contains a report by Sticker of the recovery of a case of leukæmia by oxygen treatment.

The patient was in good circumstances, and up to his twenty third year enjoyed sound health. He then began to suffer from indigestion, a sense of oppression on the chest, hoarseness now and then and rapidly increasing weakness. This condition was succeeded by frequent and copious epistaxis and urine muddy on standing. In about two years his body commenced swelling, and the weakness, difficult breathing, want of appetite and other usual symptoms, increased in severity. The spleen enlarged, forming a tumor; the liver got bigger and more resistant than normal; and the acute pain caused by percussing the lower half of the breast bone pointed to leukæmia of the marrow. An examination of the blood left no doubt as to the diagnosis.

The change seemed magical. The pallid, weak, ill-nourished, œdematous individual, who with great difficulty trailed himself into the hospital, leaning on a staff, left the ward in four months with red cheeks and lips, upright and able to walk a good few hours a day without fatigue. But the improvement was of short duration. In a few weeks he lost his appetite, his skin became pale, his feet swelled and he passed the greater part of his time in bed. The epistaxis returned. He got rapidly weaker. Bronchitis set in, the labyrinth of the ear be-

came affected, delusions of sight and hearing plagued him day and night, and in three months from the return of the disease he died thoroughly exhausted.

The most interesting point in connection with the case is the speedy partial recovery and swift relapse. The marked improvement in the symptoms is attributed, by the author, to the inhalation of oxygen. He carefully eliminates all the other factors, at least, to his own satisfaction, and thinks the inhalation of oxygen the cause of cure, whatever may be the explanation. The theory of action he gives is rather fanciful. The white corpuscles, lying thickly in the lung capillaries, give oxygen to the red and thus are never saturated. If these white corpuscles receive oxygen in a concentrated form, both they and the tissues receive enough of oxygen for healthy chemical work. The tissues oxidize as they ought, and the white corpuscles themselves get more vigorous constitutions, and are thereby enabled to transform themselves into red blood-corpuscles.

Another theory, however, is possible. Chlorine gas, though in a very dilute form, was inhaled along with the oxygen (owing to the method employed in getting the oxygen). Might not the chlorine also have some part to play in the cure? Experiments in this direction would be interesting.—*Medical Chronicle*, August, 1888.

Treatment of Septicæmia.—In a case of septicæmia occurring during a pyopneumothorax, where the patient presented the gravest symptoms of poisoning, Moizard obtained a cure by injecting in the pleural sac an ounce of an antiseptic solution whose formula is the following:

R.—Tinct. iodi. }
Alcohol., } . . āā ℥ij.—M.
Liq. potass. iodidi (1 : 10) }

With the exception of a slight and transient pain, the patient experienced no suffering and made a rapid recovery.—*L'Union Médicale*, August 11, 1888.

Abnormal Growths on the Skin.—Such formations as warts and horny excrescences are treated very successfully in the following manner: The growth and surrounding tissue is first cleansed with a solution of boric acid, and then thickly covered with crystals of pure salicylic acid over which a band of lint is placed, the whole being enveloped in gutta-percha dressing. At the expiration of eight days the coverings are removed and the growth found to be shrivelled and completely detached, the underlying skin showing no trace of hemorrhage or cauterization.—*L'Union Médicale*, August, 1888.

Antipyrin for Hemorrhoidal Ulcers.—Schreiber (*Therap. Monatsh.*, July), acting upon a suggestion of Neudörfer, used, with success, antipyrin for hemorrhoidal ulcers, after alum, zinc, morphine, cocaine and belladonna had failed to give permanent relief. The remedy was finely powdered and applied to the injured surface. The contact caused slight pain, lasting about thirty seconds. The powder distributed itself and in ten minutes the surface became moistened. By this time, the pain was markedly diminished. The patient improved. The application was followed by a quiet night and the itching was reduced to a minimum. The drug was first applied once daily, then twice daily. After twenty days, the ulcers had cicatrized. They have not since reopened, nor had new ones formed.

"The statements of Neudörfer that the analgesic and antiseptic properties of antipyrin are more important than its antipyretic, and that it deserves the synonyms of anodynin and asepsin are confirmed by this case."

Sulphurous Acid Fumigation in Pertussis.—Dr. Manby speaks highly of this plan of treatment. The children are in the morning put into clean clother and removed elsewhere. All their clothes and toys, etc., are brought into their bed-room and sulphur is burnt upon a few live coals in the middle of the room. The fire is allowed to remain in the room for five hours, and then the windows and doors are thrown open. The child sleeps in the room the same evening. About 25 grammes (a little under an ounce) of sulphur to every cubic metre may burnt; this is equivalent to rather more than 10 grains per cubic foot. The additional precautions was taken of having the day-room fumigated in a like manner during the night; the children practically lived in an atmosphere of diluted sulphurous acid gas for some days, while in several cases I had the process repeated at the end of a week.

In every instance, without exception, my observation leads me to look upon the method as a practical cure for whooping-cough. There is no doubt about it; mothers and nurses all agree with me that an immediate improvement is effected. Cough is lessened in frequency, expectoration of the thick clogging mucus much facilitated, paroxysms lessened in violence and sickness after them, as a consequence, scarcely known. The children pick up quickly, and in no case has the caugh lasted in its form of reduced violence more than a fortnight after the treatment commenced; it gradually but surely abates and ceases. I have had no specially severe bronchitic or pneumonic complications to deal with in the twenty or more cases in which I have applied the treatment, but I do not think I should desist if such complications existed.—*Practitioner*, August, 1888.

Eucalyptol and Idoform in Skin Diseases.—In attempting to prove the value of these drugs, administered together, hypodermatically, in the treatment of lung diseases, Maison has found that they are of especial value in cutaneous affections. They seem to be especially indicated in the squamous variety. In one case of ichthyosis he obtained great improvement. The dose of iodoform should not exceed two grains, given once in three days.—*Journal de Médecine de Paris*, August 12, 1888.

The Relations between Deafness and Albuminuria.—Gelli (*Semaine Médicale*, No. 13, 1888) reports the case of a patient, under treatment for paralysis of the right vocal band, suddenly affected with total deafness, a careful examination of the ear showing nothing abnormal; an analysis of the urine, however, disclosed a small amount of albumin; eighteen months later, the patient died, with symptoms of chronic Bright's disease, having never recovered the power of hearing. The case illustrates the fact that sudden, complete and incorrigible deafness may set in, without any peripheral injury of the ear at all. Under such circumstances, the attention of the physician should always be directed to some existing general dyscrasia. As to the genesis of the albumin-

uria in his case, Gellé believes there was a connection with the paralysis of the vocal band, which in its turn was due to a paralysis of the recurrent laryngeal nerve by a mediastinal tumor. The author believes that the inflammatory irritation of the recurrent exerted a reflex influence upon the nervous centres with bulb. Henriot, from a case in which diabetes mellitus existed in a patient with a tumor in the course of the vagus nerve, believes such influences as pathogenetic of diabetes mellitus, too.—*Medicin. Chirurg. Rundschau*, August 1; from *Monatsschr. F. Ohrenheilk.*, No. 6, 1888.

Paquelin Cautery in Epididymitis.—According to Dr. Brewer, excellent results are derived from the use of the Paquelin cautery. He has employed this method in forty-six cases, and in two cases only was it necessary for the patient to remain in bed after the first application, and in one the real cause of the enforced rest was a coexisting cystitis. The details of the procedure, according to Dr. Halsted, who first suggested it, are as follows: The cautery point is heated to a white hot temperature, and the surface of the skin overlying the affected organ is then lightly touched with the cautery. The operation requires only a few seconds, and need not be more than moderately painful. A dressing of iodoform ointment is then applied, and the patient is instructed to wear a suspensory bandage. Instant relief from pain is said almost invariably to follow the employment of this treatment, and the patient, as a rule, is able to be up and walk about in comparative comfort. The author adds that he has also found that marked relief from pain in gonorrhœal rheumatism can be obtained by a similar use of the cautery and iodoform ointment.—*Medical Press*, August 1, 1888.

Varieties of Diphtheria. Remarks upon Treatment.—During an epidemic of diphtheritis in Hedemarken, Bryhn (*Norsk Magaz. for Largeoid.*, 1888, No. 5) observed several cases of gangrenous erysipelas, clearly originating in diphtheria. In an isolated village in which a physician was treating a child with an extensive diphtheritic deposit in the fauces, a girl in a neighboring house, who had a couple of ulcerated fingers, was found to have an erysipelatous swelling on one labium majus, with a black crust between this and the original crease. Her throat was not involved. Later on, two sisters of the first patient were attacked with ordinary diphtheria. It transpired that the mother of the girl with gangrenous erysipelas of the vulvæ had had a sore breast two weeks before, and that the girl with diphtheria had washed linen from the neighboring house, with which the wound was covered. The woman had elsewhere nursed a child which it was said had died of diphtheria. Four others visited the sick child. One, at first had a red swelling on one finger and, later, symptoms of laryngeal diphtheria; another, a gangrenous spot upon the thumb, without other diphtheritic deposits.

In the treatment, the author recommends a warm twenty per cent. solution of boroglyceride, applied to the places on the throat from which the membrane has been previously removed, Besides a gargle consisting of fifteen parts of benzoate of sodium, five of oil of eucalyptus and seventy-five of water is used, which in appropriate cases may be employed to wash the nasal cavity. Internally, five to fifteen drops of a spirituous solution of perchloride of iron, in a teaspoonful of water, are given every two hours. The treatment often leads to a successful result in three or four days, even in severe cases.—*Medicin. Chirurg. Rundschau*, August 1.

Physostigma in Tetanus.—A case of transmissable tetanus, occuring in a lad of nineteen years, and cured by use of physostigma is reported in the *Lancet* for August 18.

The patient received a lacerated wound on the outer side of the right hand which was dressed antiseptically and did well for about ten days. At the end of that time he complained of a sore throat and stiff neck and tetanus rapidly developed. The angles of the mouth were drawn up and the masseters very rigid. Mastication impossible. One grain of the extract of physostigma was given every hour, subsequently increased to two grains hourly. Under the treatment the spasms grew less and the patient ultimately recovered.

Diabetic Coma.—On the hypothesis that this is largely due to oxybutyric acid, M. Lépsine treats it with alkalies. He saturates a quart of water with citric acid and adds an ounce of bicarbonate of sodium. The frequency and dose to be regulated by the severity of the symptoms. Under this treatment the oxybutyric acid disappears from the urine and other untoward results are avoided.—*Gazette Hebdomadaire des Sciences Méd.*, August, 1888.

Oxalate of Cerium for Sea-sickness.—Of all remedies which have been recommended for sea-sickness, Gardner (*Allg. med. Centr. Ztg.*, No. 53) has found none so well adapted as oxalate of cerium. He recommends doses of from nine to eighteen grains, in a tablespoonful of water, every three hours. In these doses the remedy is well borne. Much smaller doses were used, but they failed. In a case of aggravated indigestion he gave the patient five doses of five grains each, at intervals of two hours. In a severe attack of cardialgia the patient took eighteen grains and secured relief. In another case, one of gunshot wound of the abdomen, persistent and obstinate vomiting set in, probably from injury of some branches of the solar plexus. Nine grain doses afforded great relief. The author has, besides, used the remedy in hundreds of cases of migraine, nausea and vomiting of pregnancy, etc., with the best results. For adults average doses of nine grains are requisite. In this amount he has found the drug useful for the harassing cough of phthisis. The mode of action is not certainly known, but it is believed to depend upon a sedative influence upon the vagus and sympatheticus nerves. Untoward action has not been observed even when twenty-two grains were given in twenty-four hours.—*Wiener med. Presse*, No. 30, 1888.

Volatile Alkaloids of Cod-liver Oil.—Among the six alkaloids of cod-liver oil, Gautier and Mourgues have found that butylamine increases the functions of the skin and kidneys, and in large doses produces stupor and vomiting.

Amylamine increases the urinary secretion and the reflex activity, and in large doses induces convulsions.

Dihydrolutine is more poisonous and diminishes the general sensibility. Large doses given to quadrupeds cause a profound depression, broken by periods of excitement and paralysis of the rear limbs.—*L'Union Médicale*, August 11, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 8, 1888.

PROPHYLACTIC MEASURES AGAINST TUBERCULOSIS IN CATTLE.

AT the recent French Congress for the study of tuberculosis, certain propositions were presented by the President, M. Chauveau, and adopted, which relate to special prophylactic measures necessary to be observed in dealing with the contagious diseases of domestic animals, especially those which may be transmitted to man. The French government, upon the adjournment of the Congress, with commendable alacrity, adopted regulations suggested by the action of the Congress, which are to be enforced for the prevention of the transmission of tuberculosis from animals of the bovine species. Cattle are to be placed under the supervision of sanitary veterinary surgeons, and animals found to be tuberculous are to be isolated and sequestrated, and when killed must be killed in the presence of the inspector, who must make a post-mortem examination. Meats obtained from such animals, when the lesions are definitely ascertained, are excluded from sale, and are not even to be fed to animals, but must be destroyed. The sale of milk from tubercular cows is forbidden, though after being boiled it may be fed to animals.

In the census report of the United States for 1880, pulmonary consumption stands first in point of frequency upon the list of deaths from all diseases. This great enemy of the human race is steadily slaying its thousands, without popular comment or without inciting any well-directed effort to limit its progress. The appearance of yellow fever, cholera or smallpox in a community throws the country into alarm, and no effort is spared to restrict their spread. Yet the deaths from these diseases are inconsiderable in comparison with those from tuberculosis. Some years ago the National Board of Health started investigations of the diseases of domestic animals liable to be transmitted to the human race, and the inquiry gave promise of tangible results, but it terminated with the existence of the Board. The general government is now pursuing an inspection of cattle with the view of detecting tubercular animals and preventing the spread of disease among the herds; but this service is based upon a law limited in its provisions and which does not compare in scope and completeness with that just formulated by the French government.

Tuberculosis being recognized as a contagious disease and in all probability transmissible from animals of the bovine species to man, it is the duty of the State or general government to enforce stringent measures directed against the spread of this disease, and forbid the sale or use of meats from animals affected by it. As it is probable that infection is conveyed by alimentation, particularly by milk, the sale and use of milk from tubercular cows should be forbidden. In the absence of such a regulation, or its enforcement, safety lies in the practice of boiling the milk before using it.

ARMY MEDICAL EXAMINING BOARD.

SINCE the notice in our issue of August 11th, that this Board would be convened in New York on October 1, 1888, we have received several letters asking for further information in regard to it. It is very natural that those at a distance who are thinking of presenting themselves should desire to know something of the scope and requirements of that examination, before incurring the expense of a long journey. We are glad to be able to inform our readers on the subject.

Some conditions preliminary to the examination were given in the notice above referred to—these should be borne in mind. The physical examination comes first and, we are told, is rigid. The hardships and exposure incident to the military service require a vigorous frame, robust health, the full use of all the senses, and a vitality unimpaired by hereditary tendencies or by excesses.

The preliminary examination is designed to ascertain if the candidate has such general knowledge as

will enable him to associate with educated people with credit to the medical department. It includes arithmetic, geography and history, especially, of the United States, and general literature. A more extended and varied knowledge is much desired, but these are essential. The candidate's knowledge of chemistry and physics must be such as to furnish a good foundation for the more strictly professional branches, such as physiology and hygiene, which, it will be conceded, depend greatly upon them.

The professional branches examined on are those usually reckoned as such in medical colleges, but hygiene is given more attention than it often receives in the schools. The necessity for a knowledge of this subject for military medical men, whose duties are conspicuously those of sanitary officers, is obvious. An intimate acquaintance with the so-called specialties is not required, but the candidate's knowledge of them must be sufficient to enable him to recognize cases that may occur in his service, often isolated and distant from opportunities for consultation. He should be, we take it, a well-rounded general practitioner.

The candidate's knowledge of Latin must be sufficient to enable him to write a prescription correctly, and to use intelligently the technical terms used in medical science. Certainly less could not be expected. More extended acquaintance with the classics, a knowledge of the modern languages and of special branches of science, though greatly desired in a candidate, are not essential to success. Their possession does, however, give advantage in relative standing among those equally well prepared in medicine and surgery.

Preference is always given to applicants who have had experience in practice, especially in hospitals. We understand that the examination, both preliminary and professional, is largely a written one, but that it always includes examination at the bedside and in operating on the cadaver.

In conclusion we can confidently assure all who propose to present themselves that this examination is thoroughly impartial. Every man is judged by his merits alone, and no political, personal or social influence can affect the action of the Board.

On another page we present the communication made by M. Pasteur to the Academy of Sciences of Paris concerning the alleged discovery by Dr. Gamaleïa, of Odessa, of an attenuated virus which confers immunity from cholera. In France this is claimed as a brilliant confirmation of the two great principles of the experimental method of Pasteur, that of progressive virulence, and of chemical vaccine. Dr. Gamaleïa was a student for many months in Pasteur's laboratory and is entirely familiar with the mode of preparation of virus for vaccination, and particularly of that of hydrophobia, as practised there.

The arrangements for the First Congress of American Physicians and Surgeons, which is to meet at Washington on the 18th, 19th and 20th of this month, are complete, and the entire programme, covering a quarto-pamphlet of forty-eight pages, has just been issued. The indications are of a large representative gathering, and we understand that a number of gentlemen from abroad have indicated their intention of participating in the meeting. The list includes Sir Spencer Wells, Sir Andrew Clark, Sir William MacCormac, Drs. W. O. Priestly, William Ord, Graily Hewitt, Grainger Stewart, Mr. Lawson Tait, Mr. Victor Horsley, Mr. Thomas Bryant, Mr. Thomas Annandale, Professors Ferrier, Esmarch and Gerhardt, Drs. Reverdin and Rafael Lavista.

The Congress will transact no business during the meeting, not even electing officers. Dr. Billings has been selected by the Executive Committee to preside over the Congress, and the President of the next Congress will be selected in a similar way. The object of the meeting is solely the discussion of topics relating to medical science, and the detailed programme gives promise of a most instructive and successful meeting.

The Mississippi Valley Medical Association will meet in Pickwick Theatre, Jefferson and Washington Avenues, in St. Louis, September 25, 26 and 27, 1888, two weeks later than first announced.

This date was selected in order that the cheap railway rates during the Carnival season of St. Louis might be made available.

The Editorial Committee of the New Austrian Pharmacopœia has completed its labors. The new work will probably be published during the course of this year and go into operation at the beginning of the next.

A case of rabies in the horse is reported to have occurred at Brooklyn, New York; the attack supervening upon the bite of a dog known to be rabid,

after an interval of incubation of thirty-six days. After the full establishment of the disease it was observed that the frenzy was especially prompt and characteristic, at the sight of water or some other glittering object. The horse became utterly unmanageable, kicking and plunging, and snapping violently with the jaws, two or more of the teeth being broken by the violence of this spasmodic action; he occasionally emitted paroxysmal outcries, somewhat similar, it was thought by some, to the bark of a dog. In the end, it became necessary to destroy the animal by shooting in order to abbreviate his agonies. The case was seen by numerous experienced veterinarians of the locality, who were unanimously of the opinion that the disease was quite properly described as equine hydrophobia, the causation of which was the bite of a mad dog, the symptoms declaring themselves at the end of the fifth week.

DR. JAMES E. REEVES, of Chattanooga, formerly of Wheeling, West Virginia, will make an inspection of the State and municipal quarantines along the southern border, under instructions from the State Board of Health of Tennessee.

LEWIN (Berlin), Kaposi (Vienna), Pick (Prague) and Neisser (Breslau), are taking the initiatory steps for a Dermatological Congress to be shortly held at Berlin.

PROF. LEHMANN has declined the proffer of the Chair of Hygiene at Giessen, as the faculty and board of directors of the University of Würzburg have acceded to his request for the establishment of an institute of hygiene.

DR. SAHLI, of Berlin, has been made ordinary professor and director of the medical clinic at Berne, in place of Prof. Lichtheim, who has been called to Königsberg.

AT an Annual Meeting of the New Brunswick Medical Society held at St. John, in July, a paper on Leprosy was presented by Dr. G. A. Hetherington, who has recently inspected the lazaretto at Tracadie. He exhibited photographs, taken by himself, of the hospital and its inmates. He stated that, while the larger proportion of lepers in the province find their way to the lazaretto, there are still a considerable number of them at large in the district along the Bay of Chaleurs, and he recommended that the necessary steps should be taken to have them confined to the hospital.

THE Mayland Institute of Science, Art and Literature has offered the following prizes upon medical subjects, for which others than Italians may compete: 1. First Prize Cagnola ($300 and a gold medal worth $100): The history of hypnotism; a critical investigation of all that pertains to the subsubject, and a record of private experience. To be received until April 30, 1889. 2. Second Prize Cagnola ($300 and a gold medal worth $100): A thoroughly supported explanation of the efficacy of pellagra, or upon the nature of the miasmatic and contagious poisons. To be handed in by December 31, 1888. 3. Prize Fossatis ($800): Upon the embryogeny of the nervous system or of a portion of it in mammals, with illustrations of original investigations. To be sent in by April 30, 1890. Particulars may be had from La Segreteria del R. Instituto Lombardo di Scienze, Lettere ed Arti, Pala 770 di Breza, Milano.

A BACTERIOLOGICAL laboratory will be established at the University of Königsburg, in conjunction with the pathologico-anatomical laboratory. Prof. Baumgarten is expected to assume charge of the new department.

REVIEWS.

PTOMAINES AND LEUCOMAINES; OR THE PUTREFACTIVE AND PHYSIOLOGICAL ALKALOIDS. By VICTOR C. VAUGHAN, Ph.D., M.D., Professor of Hygiene and Physiological Chemistry in the University of Michigan, and Director of the Hygienic Laboratory; and FREDERICK G. NOVY, M.S., Instructor in Hygiene and Physiological Chemistry in the University of Michigan. 8vo. pp. 316. Philadelphia: Lea Brothers & Co., 1888.

WE have perused with much pleasure this well-written volume, which discusses subjects of great practical and scientific interest to the physician, and especially to the toxicologist and pathologist. The discovery of the ptomaines has opened a new era in the toxicological chemistry of the alkaloids, and has very materially modified medico-legal investigations in cases of alleged poisoning by these bodies. It was formerly a comparatively easy task for the expert to determine, in a dead body, the presence or absence of one of the alkaloids, by the recognized chemical and physiological tests; but it is now vastly complicated by the circumstance that there may be present, in the manipulation, one or more of these most inconvenient *ptomaines*, which, from their close resemblance to the alkaloid sought for, may very seriously embarrass the result. Fortunately, however, the difficulty of the diagnosis is not insurmountable, and the proper methods to be adopted are detailed in the present work.

The chapter describing "Foods containing Poisonous Ptomaines" is full of practical suggestions. In it the authors show that those obscure, and hitherto unex-

plained cases of narcotic-irritant poisoning arising from eating certain articles of food supposed to be perfectly innocent, such as milk, ice-cream, cream puffs, canned provisions and cheese, are in reality due to poisonous ptomaines, generated under peculiar conditions by specific bacilli acting on the complex organic material. From all the above mentioned articles of food distinct ptomaines have been extracted. Among others is one of much interest, discovered by Professor Vaughan in cheese, in 1884, and named by him *tyrotoxicon;* and subsequently also found in certain samples of milk and ice-cream which had produced poisonous, and even fatal results.

Another interesting phase of this subject is "The Relation of Ptomaines to Disease," which is very clearly stated by the authors. The bacterial origin of infectious diseases is now pretty generally admitted; but the theories of the bacterial agency have not been so thoroughly settled. The idea advanced by our authors seems to us to be the correct one,—that the disease is not caused by the direct action of these microörganisms on the blood, nor by "their consuming the proteids of the body," but by the generation of one or more ptomaines—chemical poisons—which, by absorption into the blood, affect the great nerve-centres, the heart and lungs and thus produce the characteristic morbific effects. Each disease is believed to have its own special pathogenic bacillus, which is supposed to be capable of generating its own characteristic poison or poisons.

That this is not mere theory is shown by the fact that the bacteria of different disorders will furnish, by pure culture in various materials, these peculiar ptomaines, which, when injected into different animals produce very many (though perhaps not all) of the characteristic symptoms of the particular disease. This has been absolutely proven in the case of the bacilli of anthrax, cholera, typhoid fever and tetanus, each of which has furnished, by culture, and subsequent extraction by chemical means, its own peculiar ptomaine or ptomaines. These facts, of course, open up a wide field to the pathologist; and also, we may hope, will suggest a useful, practical one to the therapeutist.

The "Modes of Extracting Ptomaines," together with their "Chemistry," are fully and ably discussed in two separate chapters; but these do not specially claim our notice here.

The two chapters on "The Chemistry and Pathological Importance of the Leucomaines" our space will permit us to notice only very briefly.

By *leucomaines* are understood "those basic substances which are found in the living tissues, either as the products of fermentative changes, or of retrograde metamorphosis." With some of these bodies we have been familiar in the past—such as creatine and creatinine, together with their derivatives, as also with the uric acid group. The researches of Gautier, Selmi and other investigators have revealed the existence of many other similar leucomaines, procured from the urine, muscular flesh and other animal, and even vegetable tissue. Among the most interesting of these, and of special importance to the sanitarian and physician, are the poisonous products obtained from expired air, as lately shown by the experiments of Brown-Séquard and R. Wurtz.

The *origin* of these leucomaines is undoubtedly to be ascribed to the metabolic changes constantly going on in the living body, by which the complex proteid molecule is split up into successive products, until it reaches its final conversion into urea, ammonia, water and carbonic acid. This incessant metabolic change appears to be an essential condition of organic life; and the elimination of the numerous resulting poisonous leucomaines from the economy, or their destruction or neutralization within the economy, seems to be amply provided for in the healthy organism; whilst any disturbance of its normal, healthy activities is sure to be followed by disease, in consequence of the retention of these morbific products.

We may congratulate the authors of this work on its intrinsic merits, and on its mode of execution; and at the same time we can cordially recommend it to the study of the profession.

SOCIETY PROCEEDINGS.

CONGRESS ON TUBERCULOSIS OF MAN AND ANIMALS.

Held in Paris, July 25 to 31, 1888.

(*Specially reported for* THE MEDICAL NEWS.)

(Concluded from page 248)

JULY 31ST.—MORNING SESSION.

EARLY DIAGNOSIS OF PULMONARY CONSUMPTION.

M. ESPINAY CAPO, of Madrid, said that one of the important points to consider in the diagnosis, is the study of the development of the thorax. If the circumference of the thorax in the mammary line is not half the height of the individual between eighteen and twenty-four years of age, this is sufficient to establish a diagnosis; if the circumference of the chest at the mammary line is not above thirty inches, we must suspect diminished pulmonary capacity, also if the distance between the two nipples is not more than seven or eight inches, if the xiphoid circumference is not above thirty-two inches, we can suspect a more or less advanced tuberculosis. He also thinks that the sphygmograph can help us very much, and believes it affords one of the surest diagnostic signs; the first signs of tuberculosis have a certain influence on the descending line of the sphygmogram, on the dicrotism.

EXPERIMENTS ON ANIMALS IN THE DIAGNOSIS OF SCROFULO-TUBERCULOUS LESIONS OF MAN.

M. ARLOING called attention to the case of a young lady, of most healthy appearance, who suffered from a suppurative adenitis; rabbits were inoculated with the pus coming from the lesion and died tuberculous; the young lady also died later on from a miliary tuberculosis. He finds also a difference, when inoculations are made from attenuated tubercular adenitis in different animals, in some instances pus obtained from these lesions produced tuberculosis in guinea-pigs but not in rabbits; the same results he had obtained from inoculation made with pus from a middle ear suppuration, and yet all these patients have shown no trace of tuberculosis.

In another series of experiments, inoculations were made on rabbits and guinea-pigs from pus obtained from

an axillary suppurating adenitis, while no other symptoms of tuberculosis could be found. Both rabbits and guinea-pigs died of the disease, and the patient, also, later on from tubercular meningitis. He has been unable to establish any difference between the two viruses used; he thinks that there is only a different grade of virulence of the same virus, which is not due to different micro-organisms.

These diagnostic inoculations enable us to make out whether or not we have to deal with tubercular lesions, their degree of virulence, etc.

As regards local tuberculosis, out of seventeen patients eight were diagnosed as scrofulous, nine as tuberculous. Out of these eight scrofulous patients, who were diagnosed as such, inoculation in rabbits having given negative results, four never returned for examination, probably on account of having been cured by the operation, two kept well and two others remained questionable as to success. Of the nine tuberculous who were considered as such, having produced general tuberculosis in rabbits, two died, four presented suppuration eighteen months later, two never returned, one is cured or much better.

M. DAREMBERG has produced local tuberculosis in old rabbits and general tuberculosis in young rabbits, with a culture that had remained for some days at the temperature of the room.

M. LELOIR attached great importance to the mode of inoculation. He having introduced fragments of lupus under the skin of a rabbit he had negative results; but having placed these fragments in the anterior chamber of the eye, he succeeded. The rabbit being an expensive animal, he experimented on guinea-pigs, and found that inoculations of lupus under the skin produced no results; while those inoculations made directly into the peritoneum gave general infection at a later period—several months—four to five. When his inoculations were made at the same time in the peritoneum and skin, by placing a fragment of lupus in the peritoneum, which came out at the wound with a piece of epiploon, he obtained local tubercular lesions of the skin. This method of inoculation he has called "hypodermo-epiploid insertion." The development of the bacilli is probably accounted for by the great vascularity of the epiploon.

M. NOCARD does not believe that tuberculosis and scrofulosis are two different diseases, he thinks they are derived from the same microbe, which is attenuated in one case, virulent in the other; perhaps also the very limited number of bacilli in scrofulosis explains their comparatively mild action as regards the lesions, which contain them in great quantities.

ON INNATE AND ACQUIRED TUBERCULAR OPPORTUNITY.

M. LANDOUZY said that we all know that certain individuals are born with all the attributes necessary to become consumptive; these constitutions we ought to study closely, for they are important in a prophylactic as well as in a therapeutical point of view. He has already described a type, which he has called "Venetian," and prone to tuberculosis; this type is characterized by very thin, smooth, white skin, hairs of a red hue, blue eyes, and quite stout; these subjects must not be allowed to live in contact with tubercular patients, for if the disease places it hands on such persons it will prove to be particularly severe.

As regard the acquired opportunity to tuberculosis, in the first rank is variola (smallpox); a smallpox patient becomes a candidate for tuberculosis. Out of more than three hundred patients who had had variola he did not find ten who were not tuberculous, and these belonged to the higher classes of society; three of them were cardiac patients, and we know the tendency of arterio-sclerotic patients to be free from tubercular infection. Hence let us never place a variolous individual in contact with consumption; for his part, he does not allow or accept any variolous nurses in his wards, on account of this sensitiveness to the disease peculiar to them; this is an additional reason why the Government should make vaccination obligatory and by so doing destroy one of the favorite fields for the development of tubercle.

EVENING SESSION.

At this meeting, several short communications were made, in regard to the

TREATMENT OF TUBERCULOSIS,

but no new reliable methods were presented.

M. LUTON, of Reims, maintained that he still obtains good results from the use of salts of copper.

M. M. JORISEMME and CHAUVIN, of Liege, have used iodoform quite extensively.

M. LEGROUX uses the pulverized vapor of creasote 20 to 1000, in a closed room.

M. FREMY, of Nice, claimed superiority for the treatment in closed hospitals, where the patients are submitted to a very strict observation.

M. RAIMONDI, of Paris, advocated the use of hydrofluoric acid in tuberculosis.

M. ROUSSEL, of Paris, urged treatment by subcutaneous injection of eucalyptol and arseniate of strychnine.

THE PRESIDENT, M. CHAUVEAU, finally presented the following

PROPOSITIONS,

which the Congress adopted.

1st. It is necessary to place in the jurisdiction of the Boards of Health all questions having a relation to the contagious diseases of domestic animals, including even those that to-day do not appear to be transmitted to man. To vaccinia, glanders, hydrophobia, malignant carbuncle, tuberculosis, other infectious diseases can be added later, which will necessitate the same precaution.

2d. It is necessary to use every possible means, including indemnities to the owners, for the general application of the principle of seizing and destroying totally all meats derived from tubercular animals, whatever may be the extent of the specific lesions found on those animals.

3d. It is necessary to print simple instructions which are to be distributed in all cities and villages, and in which are contained the methods to prevent tubercular infection by alimentation, particularly by milk, and the manner of destroying the virulent qualities of the germs contained in the sputa, linen, beds, etc., of consumptive patients.

4th. The cow-houses must be especially placed under the watch of an inspector, especially those that produce and furnish the milk used in alimentation, so that the contagious diseases from which they may suffer, should not be communicated to man.

5th. That tuberculosis be inscribed in all the sanitary laws or regulations of the world, as a contagious disease, necessitating special prophylactic measures.

ADJOURNMENT.

The Congress then adjourned, after having elected unanimously, for the next Congress which is to take place in two years, Prof. Villemin, of Paris, as president.

REGULATIONS PROMULGATED BY THE FRENCH GOVERNMENT.

As soon as the above propositions were voted by the members of the Congress, the French Government adopted the following regulations in regard to tuberculosis, which are to be enforced:

As soon as tuberculosis is recognized in animals of the bovine species, the Prefect shall order the animal or animals to be placed under the care of a sanitary veterinary surgeon.

Any animal found to be tuberculous, is isolated and sequestrated. The animal cannot be removed unless it be to kill him, and this killing is done in presence of the sanitary veterinarian, who makes a post-mortem of the animal and sends an official report within five days to the Prefect.[1]

Meats obtained from the tubercular animals, are excluded from sale, when:

1st. The lesions have become generalized, that is, not confined exclusively to the visceral organs and their lymphatic glands.

2d. If the lesions, although localized, have invaded the greater part of an organ, or present themselves, as an eruption on the chest-walls, or abdominal cavity.

Those meats excluded from alimentation as well as the tubercular viscera, cannot be used for the feeding of animals and must be destroyed.

The skins are to be used only after they have been disinfected.

The sale and use of milk derived from tubercular cows, are forbidden. The milk, however, can be used on the spot, for feeding animals, after having been boiled.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, June 8, 1888.

J. C. DACOSTA, M.D., IN THE CHAIR.

DR. C. B. PENROSE reported

TWO CASES OF EXTRA-UTERINE PREGNANCY; LAPAROTOMY AND RECOVERY.

CASE I.—M. C., aged thirty-two years, had had four children, the last, seven years ago, and two miscarriages, the last eleven years since. She was treated for syphilis and uterine retroversion in 1883. She applied for treatment again on February 6, 1888. She had been bleeding profusely from the vagina for thirteen days, and had suffered with continuous sharp pain in the left side for the same length of time. The pain and bleeding had started suddenly after heavy lifting. There were no signs of pregnancy. Vaginal examination revealed a small retroverted uterus and a tender cystic mass, about the size of a duck's egg, lying to the left of the fundus. Three days later the mass was again examined and found to have increased to the size of a large orange.

Laparotomy was performed February 10, 1888. The left tube was found distended at the outer half by a cyst the size of an orange. About three ounces of recent blood-clot were found in the Douglas's pouch. The cyst was very friable and easily ruptured. During the removal a considerable quantity of old blood-clot escaped into the peritoneal cavity. The left ovary was independent of the cyst in the left tube. The right ovary was cystic, and was also removed along with the right tube. The convalescence of this woman was uneventful. She has menstruated naturally since the operation. Three months after the operation her breasts became enlarged and painful and she was able to squeeze milk from them. This secretion of milk lasted for two weeks, until stopped by belladonna ointment. These mammary symptoms were the only signs of pregnancy exhibited before or after the operation, and Dr. Penrose asked if it is not an unusual occurrence for this secretion of milk to take place so long after the removal of the product of conception

CASE II.—E. B., aged twenty-eight, has had four children, the last one, a year ago; she had not menstruated since her last labor, until two months before she presented herself for treatment. She then began to bleed profusely, and to suffer with great pain in the left side. For the last few weeks the bleeding had been accompanied by the discharge of shreds from the vagina. Vaginal examination revealed a large cystic mass to the right of the uterus. Laporotomy was performed, May 22, 1888. To the right and posterior to the uterus was a blood cyst, about the size of an orange. The cyst was firmly adherent to the posterior surface of the uterus and to the right ovary and tube, and the right tube opened into the cyst.

This cannot be called a tubal pregnancy, the tube opens into the cyst. In each case there was disease of the opposite tube and ovary, the ovary being in each instance as large as a good-sized egg. The second patient is now out of bed.

DR. M. O'HARA said, in reference to the presence of milk in the first case, that he had seen one case in which milk never appeared. The mother was delivered at full term, and the child died. He did not think belladonna had any effect in arresting the secretion of milk.

DR. WILLIAM GOODELL said that anything producing irritation of the genito-urinary organs may cause the appearance of milk in the breasts. The presence of fibroid tumor may even do so.

DR. JOSEPH HOFFMAN reported a case of

PERITYPHLITIC ABSCESS ORIGINATING IN APPENDICITIS.

The patient, Mrs. B., married, with three children. When first seen she had a pulse of 128, and a correspondingly high temperature, and was unable to stir in bed without extreme pain. Careful questioning elicited the information that eight days previous she had slipped from a chair, causing severe pain thereby in the right iliac region. This continued up to the time at which he was called in, when she was compelled to take to her bed. The duration of her trouble, according to her own statement, was limited to a little more than a week, though,

[1] France in a territorial administrative point of view, is divided into eighty-six departments; the prefect is responsible to the central government for any thing that happens in his department.

in this connection, she mentioned the occurrence, previous to menstruation of an ill-smelling vaginal discharge. Examination per vaginam discovered the presence of a tumor to the right, along side the uterus, the touch of which gave her much pain. The rectum was empty, she having had a dysenteric attack the previous day. External examination was so painful that he did not attempt it. The pain in her back and right leg was intense. He decided that operation was necessary, and called in Dr. Joseph Price for consultation; but after an examination under ether he was somewhat uncertain as to the condition.

Operation being decided upon, an opening was made in the median line. The cæcal portion of the intestine was matted down and only freed with difficulty, The appendix was almost completely buried in pelvic tissue, and the temptation was great to tie it off piece by piece, though it was afterward enucleated by persistent effort. The cæcal portion of the bowel was almost gangrenous in spots and nearly ulcerated through. Surrounding this portion was a quantity of stinking pus, about two ounces. The pelvis was carefully washed out, no antiseptics being used, and a drainage tube introduced into the cul-de-sac, and a rubber tube led from the fossa through the incision, which was closed by seven deep and superficial sutures. Nothing was done with the bowel save to cleanse it. The bowels were at first moved by enemata, and after a quantity of scybalæ was discharged, calomel in one-sixth grain doses was given to clean the tongue and relieve bilious vomiting. The patient made an uninterrupted recovery, all the stitches being removed, as well as the tubes, by about the tenth day. The patient now, at the twenty-fourth day, is sitting up, entirely free from pain.

A curious feature of the case was that in three days after removal of the offending appendix, the patient remarked that she had not been so free from pain for two years, and then went on to give an exact history of her trouble, all of which pointed to perityphlitis.

The points, principally, to which attention may be called are the closing of the incision and the location of the same. Although central, drainage was perfect, and though sutured, it promptly healed, showing he thought that dogma, both as to location and to allowing the incision to remain open, is not wise. As in this case the central incision enabled them to remove at the same time an ovarian hæmatoma, otherwise out of reach, and as drainage was perfectly obtained, these points for such operation are worthy of special consideration.

Dr. Charles B. Penrose asked whether or not the pus was encysted around the cæcum or free in the peritoneal cavity.

Dr. Hoffman said the pus became evident only on reaching the cæcum.

Dr. Penrose said that the cases in which it is proper to make an incision over the cæcum are those in which there is an encysted abscess around the cæcum or the appendix. If there is free pus in the peritoneal cavity, a median incision would probably be better.

Dr. Goodell said that he, on several occasions, had been obliged to sever the appendix from its attachment, in operations for the removal of ovarian tumors, and the operation has seemed to have no effect. It seems to be a useless appendage. He did not know that modern research had thrown any light upon its use. In removing the appendix he simply ligated it with silk and cut it off, carefully squeezing the end so that no fecal matter should remain.

Dr. Joseph Price said that a few years ago ovariotomists regarded the appendix as sacred, as something that should never be touched. His case is of great interest. She had complained for two years, her trouble evidently beginning in an appendicitis. The cæcum was so much thickened and so low down in the pelvis as to suggest tubal disease. She, however, had a good history and several healthy children, the youngest being two years of age. The presence of the tortuous body on the outside determined the choice of the median incision. On opening the abdomen, a small hæmatoma was first removed, afterward the cæcum was dealt with. The course of the case was all that could be desired.

Dr. T. G. Morton teaches lateral incision and nonclosure. As to the first, circumstances should influence the choice; as to the second, he did not believe in it at all. We are too far advanced in surgery for such procedure. He did not believe the view that perityphlitis is necessarily acute. He knew of a case of Dr. T. G. Morton in which the operation for the trouble was repeated at the end of a year, and the appendix removed. Here the trouble was recurrent, gradually growing worse and necessitating the second operation.

Dr. M. O'Hara cited, in substantiation of Dr. Price's view, the case of his own child, in which, inside of eleven months, there were two or three attacks. For four or five months he was in perfect health, although the condition (appendicitis) existed. Another attack followed and death from septic peritonitis resulted.

Dr. M. Price believed that the peritoneum can accommodate large quantities of pus for a time, just as abscess in other parts of the body can be tolerated.

Dr. William Goodell thought that perityphlitis, like any other form of inflammation, may exist for years.

Dr. Hoffman held it to be a mistake to believe that inflammation cannot be present in these without the presence of a well-defined tumor.

Dr. J. V. Kelley thought no one would diagnose perityphlitic abscess without the presence of a tumor. The pericæcal tumors undergo resolution spontaneously and abscesses do not form.

Dr. J. B. Deaver drew a distinction between appendicitis and perityphlitis, and believed that very few cases of inflammation about the appendix undergo resolution.

CORRESPONDENCE.

DIAGNOSIS OF AN EXTRA-UTERINE PREGNANCY IN THE EARLY STAGE.

To the Editor of The Medical News,

Sir: I submit the following hurriedly written notes of the case of Mrs. H. B., aged thirty-four, a well-nourished English woman, who applied for treatment at the close of the clinic at the Philadelphia Dispensary on the evening of June 22, 1888.

"Pain in the left abdomen after eating. Diarrhœa. Vaginal discharge decidedly red, after any exertion. Insomnia. Neuralgic pains in the left hip, thigh and knee. At irregular intervals pus and blood from bowels, next movement in one half hour, ordinary diarrhœal character. Examination: vulva bluish; chocolate col-

ored mucous discharge. Cervix hard; uterus enlarged—not markedly; fundus tender but fairly hard. Cystic mass to left and partly behind uterus, rising higher as it approaches ilium; very tender; pressure on it gives some pain experienced in defecation; probably hæmatocele (suppurating into bowel?)—possibly extra-uterine pregnancy. Vaginal discharge *always* dark, even when copious; is probably discharged from hæmatocele through the left tube. Has not at any time considered herself pregnant. Sent home to bed."

The following additional items were elicited but on account of the lateness of the hour they were not entered in the note book:

She had last conceived twelve years before, and had been delivered at term. She had had no miscarriages. Since then her menstrual periods have been regular in time and duration, until last April when they appeared for but one day, when, after a severe wetting, they ceased, and the patient attributed their cessation to this fact.

A month later, in May, she experienced uncomfortable sensations, but no flow appeared. There were, after this, pains in the breasts, colic and occasional vomiting. Micturition was painful but not free. As mentioned in the note, she suffered from nearly constant pain in the left, lower abdominal region, radiating to the hip, thigh and knee of the same side. At no time had she had paroxysmal shocks of pain, or exhaustion. The question was several times asked during the interrogation, whether she had at any time, during the last three months, considered herself pregnant, and her answer was, each time, in the negative.

About June 8, after having pains referred to the lower bowel, there was a discharge of bright blood, and pus from the rectum, preceded by very painful defecation which continued thereafter. Diarrhœa followed of the character mentioned in the notes. At irregular intervals the passage would consist of a chocolate-colored fluid mixed with mucus, but no fecal matter. In half an hour the dejection would present characters just the reverse, diarrhœal matter without a tinge of coloring or a trace of mucus. This seemed to point to an adventitious opening into the bowel, communicating, it was inferred, with some part of the mass to the left of the uterus. This inference was suggested by the fact that (according to the patient's statement) the colored discharge was precisely like the muco-sanguinolent flow which came from the uterus. This latter had been flowing for a number of days (the exact time cannot be recalled, as the patient was seen but once, and the notes were not as full as they should have been), was mainly constant, and was increased upon exertion.

An examination revealed a decidedly bluish discoloration, particularly confined to the vaginal mucous membrane and remains of the hymen. This line of demarcation has been frequently noticed in examining women in the early months of pregnancy. This discoloration being met with at the beginning of the inquiry, and resembling so much the like condition in pregnancy, gave a strong color to the suspicion of the latter process being in action.

Issuing from the vulva was the brownish-red mucoid discharge mentioned in the notes. The cervix was hard. It frequently is in the early period of utero-gestation, therefore its condition was not a positive index to the condition of the uterine cavity. The os was more yielding than normal, but not enlarged. The uterus was found to be slightly anteflexed; the fundus slightly enlarged, a degree softer than usual, and tender upon slight pressure, but upon careful bi-manual palpation yielding distinct evidence of being empty. No sense of fluctuation was felt, and the antero-posterior diameter was not increased. Passing to the left, there was felt a cystic mass, about the size of a large orange, smooth and equally compressible in any direction. Pressure upon it caused pain similar to that experienced in defecation. The mass extended to the wall of the pelvis, rising a little higher as it approached it. Toward the median line it extended to and partly behind the uterus, and below it dipped into the pelvic tissues on the left side to a plane nearly on the level with the os, but less deeply behind the uterus. To the touch it was evidently cystic and contained a freely moving fluid. It had not the boggy resistance given by the coagula of a hæmatocele. Gentle ballottement was tried, but without success.

Although the ordinary history of the hæmatocele was absent, there never having been the agonizing, paroxysmal pain, or the shock, pallor and depression so generally accompanying this condition, it was thought possible that some slight rupture, either of the sac itself or of some surrounding structure had taken place, to account for the blood and pus from the bowel appearing intermittently, as well as for the marked old-blood discharge from the vagina.

To review the symptoms, there were:

1. A woman, forty-three years old, who had not been pregnant for twelve years.
2. Cessation of the menses.
3. Various subjective but erratic symptoms of pregnancy, such as vomiting, pain in breasts, painful though not frequent micturition.
4. Characteristic blueness of the vagina.
5. A moderately hard uterus, with decidedly strong convictions of its being empty.
6. A cystic mass to the left of the uterus, of presumably rapid growth, and of a size conforming to the probable period of gestation.
7. Pain in the region of the growth of such character as to convince the patient of the existence of deeply seated trouble, and to cause her ready assent to operative measures for her relief.

The evidence was so strong in favor of the existence of extra-uterine fœtation, that an operation was urged, the woman was directed to go home, to avoid any over-exertion on the way there and go to bed at once.

On June 25, Dr. Joseph Price performed laparatomy, and removed a fœtus and its placenta from the unruptured cyst. Respectfully yours,

HARRIS A. SLOCUM, M. D.

PHILADELPHIA, July 30, 1888.

NEWS ITEMS.

Inoculation for Cholera.—The following is the chief part of the paper of DR. GAMALÉIA, of Odessa, on vaccination against Asiatic cholera presented by M. Pasteur at a recent meeting of the Paris Academy of Sciences:

"The author has only applied to cholera two great principles of the 'experimental method'—that of progressive virulence and that of chemical vaccine matter. It is known that the ordinary forms of cholera vibrion are so little virulent that M. Koch, who discovered them,

thought, after many failures, that cholera could not be communicated to animals by inoculation. The pupils of M. Pasteur at the time of the French expedition to Egypt only once succeeded in communicating cholera to one hen. Now it is an easy matter to give the cholera virus excessive virulence. All that is necessary is to introduce it into a pigeon after passing through a guinea-pig. It then kills the pigeon by producing a dry cholera. What is still more important is that the microbe appears also in the blood of the pigeons. After a few passages this microbe acquires such virulence that the blood of the pigeons in a dose of one or two drops kills all fresh pigeons in from eight to twelve hours. This virus kills also guinea-pigs in still smaller doses. It is important to note that animals of both species become victims to the infection.

"With this deadly virus we have been able to establish the existence of an immunity from cholera. Thus we inoculate a pigeon twice with the ordinary (non-virulent) virus of cholera, first in the pectoral muscles, next in the abdominal cavity. The pigeon had become proof against repeated infection by the most virulent virus in the blood of pigeons. The fact of immunity was thus ascertained.

"Now if this passage virus is developed in a nutritive broth, and is afterward heated to 248° F. for twenty minutes to kill all the microbes it contains, it is possible to show that the heat has left in existence a very active substance in the sterilized broth. This broth, in fact, contains a poisonous substance which produces characteristic phenomena in the animals experimented on. Inoculatated to the extent of four cubic centimetres to one guinea-pig, the sterilized broth produces a progressive fall of temperature, and death in twenty or twenty-four hours. On dissection there is found a swollen state of the stomach and intestines, and, as was to be expected, a complete absence of cholera microbes. Pigeons succumb in this way with the same morbid phenomena, but their death is produced only by a dose of twelve cubic centimetres injected at once. If, on the contrary, there is introduced into them the same quantity of twelve cubic centimetres, but in three, four or five days (by injecting, for instance, eight cubic centimetres the first day and four cubic centimetres two days after), they are not killed. There is, besides, shown to exist in these pigeons a phenomenon of the highest importance. They have become proof against cholera. The most virulent virus —the blood of a pigeon inoculated even to the amount of half a cubic centimetre—is no longer able to kill them.

"The vaccination of guinea-pigs is still more easily carried out by introducing into them the poisonous and vaccinating broth in a quantity of two cubic centimetres. They are vaccinated at two or three sittings. Thus we find here a method of vaccination for the prevention of cholera. The method is founded, as has been shown, on the employment of sterile vaccinating matter, and it possesses all the advantages of chemical vaccination—certainty and security — as the chemical vaccinating matter can be strictly measured and introduced in doses small enough to be quite inoffensive, while the total can give the quantity desired, for complete immunity is obtained without danger and without exception. We consequently hope that this method might be applied to human vaccination to preserve the populations from Asiatic cholera."

M. Pasteur, after reading the note, stated that Dr. Gamaleïa had expressed his readiness to repeat the experiments at Paris in presence of a committee of the Academy of Sciences and to try on himself the inoffensive and sufficient dose for human vaccination. He is ready to undertake a journey into countries where cholera prevails to prove the efficacy of his method. M. Pasteur added that he need scarcely say that he accepted with the greatest satisfaction the offers to conduct the experiments in his laboratory made by Dr. Gamaleïa.

The letter was referred to the committee, which has a prize of 100,000 f. in its hands for a cure for cholera, and it was arranged that the experiment should be postponed till November.

The Yale Thermometric Bureau.—The thermometric bureau established, in 1880, in connection with the observatory of Yale University, is accomplishing a work which physicians ought to appreciate. It has examined a gradually increasing number of thermometers during the years of its existence, but its usefulness is not measured by the number of instruments that pass through its hands. There is from year to year an improvement in the quality of instruments of American manufacture submitted for verification, both actual and relative to foreign manufactures, and the observatory claims a share of the credit for this improvement.

"It may now be fairly said, as it could not have been said before the institution of this bureau, that the best clinical thermometers of American manufacture compare favorably with the best foreign manufactures, both in the smallness of the amount of the required corrections and in their uniformity throughout the scale." Such was the statement of the managers of the observatory in their last year's report, and this year they find occasion to say that their good work is still progressing.—*Boston Med. and Surg. Journal.* Aug. 16, 1888.

Artificial Fecundation.—Since the Abbé Spallanzini in 1767, fecundated bitches, and Hunter, later on (1799), succeeded in rendering a man with hypospadias a happy father, the operation of artificial fecundation has passed through many different experiences, which has brought it more than once before the tribunal of both public opinion and the laws of countries. Eight years ago a married couple in Bordeaux, despairing of having a family, consulted a Doctor Lajatre who, by circulars spread about the country, pretended to render sterile marriages fruitful by a special operation. The doctor performed the operation, but no results followed, and his clients refused to pay him the fee demanded—£60. He thereupon summoned them before a magistrate, but this worthy representative of the law, after listening to the explanations of the doctor, which, by the way, were very minute, all the details of the operation being entered into, not only dismissed the case, but fined the plaintiff for revealing professional secrets. Further, the magistrate gave it as his opinion that artificial fecundation was repugnant to the laws of nature and a positive social danger, and that such procedures should not be put into practice.

This verdict was taken up by the Society of Legal Medicine, as it is called in France, and the president (M. Brouardel) said that the operation might be per-

formed where, after other means had failed, no reasons were found in the man or the woman to account for sterility. Encouraged by this declaration, M. Lajatre came up to Paris, where he advertised in the daily papers his method of procuring families. It will be remembered that the Paris Faculty refused to accept a thesis on this subject presented by a student called Gérard. Last year a sort of company was got up in the capital, sending broadcast pamphlets entitled *Do Vitam*. A large apartment was hired in the Chaussée d'Antin, a doctor was engaged to do the operation, and for a time all went on well. Disappointed husbands and wives came in numbers, but some disagreement took place between the parties interested, and the whole matter has now been placed in the hands of the lawyers, from which it is not likely ever to come out.—*Medical Press*, July 18, 1888.

The Book of Doctors.—In 1884 appeared Part I. of a work entitled "Biographisches Lexicon der Hervorragenden Aerzte aller Zeiten und Völker" (Biographical Lexicon of Eminent Physicians of all Ages and Nations). The special editor was Professor Gurlt, of Berlin, and the publisher Dr. August Hirsch, Professor of Medicine in the same city. The work was to be completed in six volumes in 1888. It is now complete and is spoken of as, after Eulenburg's Real-Encyklopædia, the most distinguished collective work in the domain of medical literature. For obvious reasons the biographies of living medical men are recorded in a sufficiently bare manner, little besides dates and other facts being given. The work contains biographies of 14,415 physicians, of whom a fair proportion are Germans or of a German-speaking nationality. Including Germans, Austrians, German Swiss and Russians, 5045 German medical authors have been found of sufficient eminence to claim a niche in the great gallery. The fact that the biographies of over 9000 foreign medical men are included in the work shows that the editors have not been by any means exclusive. Next in number to the Germans follow the French, British, Italians, North Americans and others. It is quite certain that no work extant can be compared with it, and as a monument of German diligence and German thoroughness it will bear the strictest examination and criticism. Although it is too much to expect that such a comprehensive work will be translated into other languages, it is something to know that such a vast amount of material has been gathered and is accessible to any who choose to make use of it.—*Medical Press*, July 25, 1888.

Death from a Poisoned Cock's Spur.—The death of an entire family of six persons, at the City of Mexico, is reported to have followed quickly after the partaking of a meal of roast fowl, the chicken having been killed at a cock fight. The illness was very rapid in its course, death taking place before medical attendance could be procured. The explanation of this strange casualty that is offered is that the spur, by which the death of the bird was caused, had been poisoned before the cock fight, and that enough of the poison was taken up and retained in the flesh of the slain animal to involve mortally a whole family.

The Treatment of Obesity.—The four principal plans for the treatment of obesity are thus summarized by the *Detroit Lancet*: The eating of nothing containing starch, sugar or fat, called the Banting system; the eating of fat, but not sugar or starch, called the German Banting; the wearing of wool and sleeping in flannel blankets instead of sheets, or the Munich system; not eating and drinking at the same time, or rather the allowing of a couple of hours to intervene between eating and drinking, or the Schweninger system.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 28 TO SEPTEMBER 3, 1888.

ALDEN, CHARLES H., *Major and Surgeon.*—Detailed as a member of the Board of Medical Officers convened at the U. S. Military Academy, West Point, N. Y., vice Major and Surgeon Charles R. Greenleaf, relieved.—Par. 2, *S. O. 199, A. G. O.*, August 28, 1888.

CALDWELL, DANIEL G., *Major and Surgeon.*—To report to the Recorder of the Retiring Board in session at Fort Leavenworth, Kansas, as a witness in the case of Captain Thomas Sharp, Seventeenth Infantry.—Par. 2, *S. O. 74, Department of the Platte*, August 18, 1888.

CALDWELL, DANIEL G., *Major and Surgeon.*—Having completed his duty as witness before the Retiring Board, Fort Leavenworth, Kansas, to return to his station, Fort D. A. Russell, Wyoming.—Par. 4, *S. O. 106, Department of the Missouri*, August 24, 1888.

LORING, LEONARD Y., *Assistant Surgeon.*—Granted leave of absence for one month.—Par. 1, *S. O. 97, Department of Arizona*, August 23, 1888.

TAYLOR, MARCUS E., *Captain and Assistant Surgeon.*—Granted leave of absence for four months, to take effect about October 15, 1888.—Par. 8, *S. O. 196, A. G. O.*, August 24, 1888.

BIRMINGHAM, HENRY P., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Myer, Virginia, and ordered to Fort Klamath, Oregon, for duty.—Par. 18, *S. O. 196, A. G. O.*, August 24, 1888.

BALL, R. R., *Assistant Surgeon* (U. S. Army, Fort Riley, Kansas).—Ordered to Fort Lewis, Colorado, for temporary duty.—Par. 5, *S. O. 108, Department of the Missouri*, August 27, 1888.

SWIFT, EUGENE L., *Captain and Assistant Surgeon.*—Upon being relieved from temporary duty at Fort Klamath, Oregon, to return to his proper station, Fort Spokane, Washington Territory.—Par. 18, *S. O. 196, A. G. O.*, August 24, 1888.

RAFFERTY, OGDEN, *Assistant Surgeon.*—To proceed from Fort Clark to the camp at the Department Rifle Range, near San Antonio, Texas, and report for temporary duty.—Par. 3, *S. O. 85, Department of Texas*, August 15, 1888.

RAFFERTY, OGDEN, *Assistant Surgeon*.—Upon conclusion of Department Rifle Competition, will report to the Inspector of Rifle Practice, Division of the Missouri, for assignment to duty in connection with the Division Rifle Competition, as Camp Surgeon.—Par. 4, *S. O. 86, Department of Texas*, August 17, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING SEPTEMBER 1, 1888.

CRANDALL, R. P., *Assistant Surgeon*.—Detached from the "Saratoga," and wait orders.

DUBOSE, W. R., *Passed Assistant Surgeon.*—Detached from the "Jamestown," and ordered to the "Constellation."

ARNOLD, W. F., Nashville, Tenn., commissioned Assistant Surgeon in the Navy, August 18th.

LUNG, GEORGE A., Canandaigua, N. Y., commissioned Assistant Surgeon in the Navy, August 18th.

VOL. LIII. SATURDAY, SEPTEMBER 15, 1888. NO. 11.

ORIGINAL LECTURES.

SKIASCOPY; OR THE "SHADOW" TEST FOR THE DETERMINATION OF THE REFRACTION OF THE EYE.

A lecture delivered before the School of Ophthalmology.

BY SWAN M. BURNETT, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE UNIVERSITY OF GEORGETOWN; DIRECTOR OF THE EYE AND EAR CLINIC AT THE CENTRAL DISPENSARY; AND OPHTHALMIC AND AURAL SURGEON TO THE GARFIELD HOSPITAL, WASHINGTON.

GENTLEMEN: In our studies of the methods of determining the refraction of the eye by means of the ophthalmoscope up to this time, we have dealt with those ordinarily employed, which gave an image, real or virtual, of the details of the fundus oculi—optic nerve entrance, retinal vessels, etc. These are the classical methods and will always remain in vogue, because of their indispensable value in general diagnosis; and for this reason they should be cultivated assiduously by all those who wish to make themselves proficient ophthalmoscopists.

There is, however, another method of ophthalmoscopic optometry, recently brought into practice, which, though based upon the same optical principles as these, differs from them in some points of practical detail. It is a method which has been enthusiastically recommended and endorsed by some, while by others, of equally good authority, it is regarded with indifference or distrust. There are those who look upon it as most inaccurate or unsatisfactory, but many regard it as probably the simplest and most trustworthy and valuable plan of objectively determining the refraction which we have at our command. The Germans use it scarcely at all; the French, among whom it originated, are divided in opinion as to its usefulness, while in England it is to-day the most generally adopted method for the ophthalmoscopic diagnosis for refraction. The eclectic character of the American is shown in this as in all other questions, and the "shadow-test" finds adherents and detractors in almost every town and city where scientific ophthalmology is practised. Its very simplicity of execution is brought forward as an argument against it, because, it is averred, if it should come into general use the other methods of ophthalmoscopic examination, particularly that by the direct method, which are so important on other accounts, would be neglected. I have yet, however, to learn, gentlemen, that simplicity is an objectionable quality in any procedure which is as accurate and reliable as others more complicated, and we have no need to fear that the determination of refraction by the ordinary methods of ophthalmoscopic examination are likely to fall into desuetude, "innocuous" or otherwise. No one method so completely occupies the field as not to allow room for one more; and even though you may adopt the shadow-test as a routine method of determining refraction, you will still find use for your refraction-ophthalmoscopes.

The method under consideration is known by a large number of names, no one of which is accurately descriptive of its underlying principles.[1]

Out of the multitude, I have selected one which seems to me, on the whole, the least objectionable and which is not likely to be confounded with anything else of a similar character.

The most prominent—in fact, the guiding—feature of the method, is the shadowy edge of an illuminated area which apparently passes across the pupillary space. In all descriptions of the method you will find that it is to this shadow bordering the bright area that attention is directed, and this being so and there being no other method of examination to which the term can be applied, the "shadow-test" seems, all things considered, about as appropriate as any that has as yet been suggested. It does not commit us to any special theory and there is no liability to confusion—two very strong points in nomenclature. If we want to be scientific and classical we may say "skiascopy" (σκιά, a shadow; σκοπέω, I look at).

The manner of performing skiascopy is very simple: Take an ophthalmoscopic mirror—plane or concave—and, holding it at a distance of forty or sixty inches (1 m. or 1.33 m.) from the eye to be examined, throw the light coming from a flame behind and above the head of the patient into the pupil. The pupillary space will, of course, appear brightly illuminated. Then rotate the mirror slightly on its vertical axis, and a brightly illuminated area, bounded by a dark shadowy edge, will appear to pass horizontally across the pupillary space. The intensity of the illumination and the direction and rate of its movement—or rather that of its shadowy edge—form the basis of the diagnosis of the refractive condition of the eye under examination.

How this is made possible it is our present purpose to inquire.

The phenomena of the shadow differ, accordingly as the experiment is made with a plane or a concave mirror,

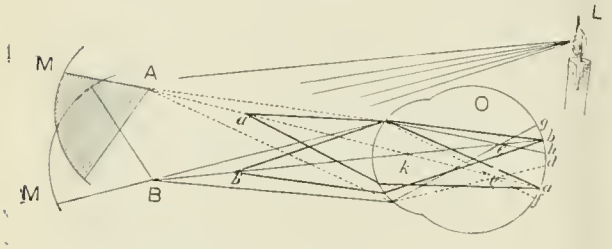
[1] It was called *keratoscopie* by its discoverer (Cuignet) and is still so-called by a number of French writers. This is a misnomer, for we do not inspect the cornea at all, and it plays only a part in the production of the phenomena. *Retinoscopy*, used almost altogether by the English, is equally incorrect, for we do not inspect the retina, but only the image of the bright image formed on the fundus, and which may not be on the retina at all, but on the optic disk. *Pupilloscopy* (*koroscopy*) is somewhat better chosen, since without a pupil to admit the light, we could have no phenomena; but it is evident that it is not the pupil we inspect or which gives us the information we seek. *Fantoscopie retinienne* is merely an approximation to the true explanation. *Retinoskiascopie* is somewhat better, while *dioptroscopie* can mean nothing, since we do not inspect, but measure, the refracting power of an optical apparatus.

the reason whereof will be very apparent when we have examined the matter a little further. We shall first study

SKIASCOPY WITH THE CONCAVE MIRROR.

When the light from a concave mirror of from 7 to 10 inches' focus (20 to 25 cm.) is thrown into the eye from a distance of sixty inches, the source of illumination is not the flame behind the head of the patient, nor the mirror itself, but the inverted image of the flame, L (Fig. 1), formed by the mirror, M, at its focus, A, which is, in this case, about forty or fifty inches in front of the observed eye, O. From this focus of illumination a cone of divergent rays proceeds, which forms a large circle of illumination on the face, a part only of the rays passing into the pupil. The light, however, that does pass in at the pupil is refracted by the optical media of the eye and finally strikes the retina.

Fig. 1.



Now, the manner in which these rays shall strike the retina depends upon the refractive condition of the eye. Let us suppose, in this instance, that the eye is myopic. In that case the rays proceeding from A will, after entering the eye, cross at *e'* and, passing on, form on the retina a diffusion image, *f d* of A, with its centre at *a*. This image, or bright spot, now becomes in its turn an illuminated object, sending out rays of light, just the same as if it were an originally luminous body. And just here is where I think many students of ophthalmoscopy find a hitch in their clear comprehension of the optical phenomena involved.

In the first place, you must remember that after the light gets into the eye and falls on the retina, the source of illumination is to be disregarded and we have only to do with the illuminated retinal surface, which might just as well have been illuminated from behind as through the pupil, as, indeed, we have already many times demonstrated to you on the artificial eye. We throw light into the eye not to get a reflection from the retina as from a plane bright surface like a mirror, but for the same reason that we open a window of a dark room, namely, to illuminate the objects we wish to see, and not to get a reflection of the sun and sky from these objects.

Another possible source of confusion, as I have found, is in the mistaken application of the law of conjugate foci. We have taught and demonstrated to you that in conjugate foci the image can replace the object, and the object the image, showing that the rays of light follow the same path going and coming. Its application in this instance, however, is not, as I have found many students to suppose, to the flame image A, and the illuminated area *d f*, but to the area *d f*, and its image at *a'*. The rays from the area *d f* do not cross at *e'* and go back to A, but diverge like the rays from any other illuminated object and, striking the refracting media in the front of the eye, are brought to a focus and form an image of it at the far point of the eye (*a'*), where an object must be, in order to have its image formed clearly and distinctly on the retina. In other words, *the retina and the far-point of the eye are conjugate foci.* We shall find this fact to lie at the basis of this method of examination and you should get it clearly fixed in your mind, otherwise there will come a point in your studies of it when you will find yourself in inextricable confusion.

Taking, then, *d f* as the illuminated object and assuming, as we have done, that the eye is myopic, an image of the area *d f* will be formed by the refracting media *in front* of the eye and at the conjugate focus of *d f*, that is, at the far point of the eye *a'*. Now the distance of the far-point *a'*, as we have learned, depends upon the degree of the myopia (that is, upon the amount of the increase in the length of the eyeball), being closer to the eye in the high degrees and getting farther and farther away as the degree decreases, until it reaches infinity, when myopia ceases and emmetropia sets in.

Suppose, now, we rotate the mirror on its axis from *M* to *M'*. The image of *L* will then move from *A* to *B*, and remaining, as before, the source of illumination, form on the retina the blurred image *g h*, the rays having crossed at *e*. The rays coming from this illuminated area *g h*, like those coming from *d f*, must come to a focus in front of the eye and form an image at the far point *b'*. In making this rotary movement of the mirror the following important changes will have been noted, viz., *that while the movement of the illuminated area on the retina has been the opposite of that of the mirror, the movement of the aërial image of this area, at the far point of the eye, has been in the same direction as that of the mirror.* If, therefore, on rotating the mirror before the eye, at a distance of sixty inches, we find the shadowy edge of the bright image to pass across the pupillary space in the same direction as the mirror, it shows that the image is formed between the mirror and the eye (at its far point), and consequently there must be M greater than 1 D. And not only that, but the amount of displacement of this aërial image, with its shadow, as compared with that of the mirror—that is to say, its rapidity of motion, will also depend upon the distance of the shadow from the eye; being slower and shorter when it is near and more rapid and more extensive as it recedes toward the mirror. The reason of this is at once apparent when we notice that the lines A *k* and B *k*, passing through the nodal point of the eye and upon which these images are formed, gradually approach as they go toward the eye and finally come together at the nodal point *k*. While, therefore, the *direction* of the shadow movement, *with the mirror*, gives us knowledge of the existence of the myopia, the relative *rapidity* of its movement gives us some knowledge of its degree, though only vaguely.

These phenomena are, of course, only possible when there is an actual aërial image of the illuminated retinal area formed between the observer and the eye under observation—that is, when, as in the case under consideration, the myopia is greater than 1.25 or 1.5 D., because when the myopia is lower than 1.25 D., the image is no longer formed in front of the observing eye, but the rays going to form it behind the mirror strike the eye of

the observer as they come immediately from the object—that is to say, the object and not its image, real or virtual, is seen; and, of course, any change in its position on the retina is observed in a direct manner; and as the movements of the bright area on the retina are the opposite of those of the image A and of the mirror, the shadow movement, in this case, will be the opposite, or *against* the mirror movement.

The same conditions are present, too, when the rays emerge parallel, as they do when the eye is emmetropic. In Fig. 2, the rays from the area at *a* emerge parallel in

FIG. 2.

the direction A, and when it moves to *b* in the direction B, and the image is at infinity, and is infinitely large. The eye of the observer, however, intercepting the rays in their course, forms the image on its own retina and sees it and its movements directly and as they are—that is, when *a* moves to *b*, from right to left, the movement appears, to the observing eye, to be from right to left.

In *emmetropia*, therefore, and in *low degrees of myopia* in which the far point is behind the mirror, the *movement of the shadow is against* that of the mirror.

We must have, necessarily, a very different set of phenomena when the eye is *hypermetropic* and the rays from the illuminated retinal area emerge divergently. (Fig. 3.) Here the bright area cannot be seen directly, as in emmetropia, or in the lower forms of myopia, nor is there a real image of it formed anywhere, as in myopia of the higher degrees.

The eye of the observer, however, placed in the path of the diverging rays, refers their origin to a virtual image, *c*, behind the eye (at its far-point, which, as you know, is negative in the hypermetropic eye), where they would all meet if prolonged backward. When the bright area is moved by the rotation of the mirror from *a* to *b*, the virtual image moves in the same direction from *c* to *f*—that is, *against* the movement of the mirror.

It will be noticed, too, that the more divergently the rays emerge from the eye—that is, the higher the degree of hypermetropia, the closer behind the eye will be the virtual image. As a result of this, the extent of movement of the shadow will be less the higher the degree of hypermetropia, gradually becoming greater as the degree increases, until it reaches infinity and the rays emerge parallel and the hypermetropia merges into emmetropia. It is easy to see that when the virtual image is at *c* and is displaced on rotation of the mirror to *f*, the extent of movement is less than when it is at *c* and displaced to *d*.

We thus see that the direction of the shadow movements, when the source of illumination is the image of a flame produced by a concave mirror held about forty inches in front of the observed eye, gives us positive and definite information as to the refractive condition of the eye, and we recapitulate it as follows:

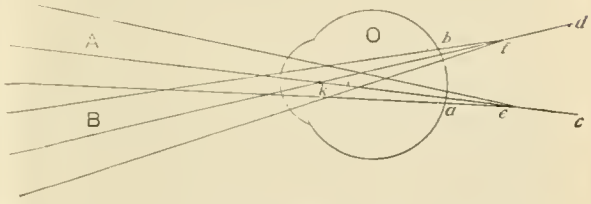
1. Movement of shadow *with* the mirror: myopia greater than 1 D.

2. Movement of shadow *against* the mirror movement: hypermetropia, emmetropia or myopia less than 1 D.

We know also, further, that the *movement is less the greater the amount of ametropia* (M. or H.).

As regards the *distinctness of the shadowy edge* and the intensity of the contained bright area, it is curious to note that diametrically opposite opinions are held.

FIG. 3.



Thus, Hartridge,[1] who is the latest English authority on the subject, says:

"It is in the lower degrees of ametropia that we get the brightest and best defined shadows. The clearness of the image and the brightness of its edge decrease as ametropia increases." (P. 87.)

On the other hand, Galezowski, in the last edition of his treatise on the eye, states:

"The shadow is darker and its movement slower in proportion as the ametropia is greater. Of these two peculiarities the first is due to the fact that the enlargement of the virtual image in H. and of the real image in M. is much less as the M. or H. attains a higher degree. The same quantity of light and shadow being distributed over less surface, the illuminated area is necessarily brighter and the shadow denser."[2] (P. 824.)

Both, it is very evident, cannot be right, and Mr. Hartridge is the more nearly correct. He neglected, however, to state that the brightest area with the best defined shadow in this method of examination is in that degree of myopia in which the image of the flame formed by the mirror lies at the far-point of the eye[3]—that is, when A and *a'* fall together (Fig. 1). This image is then at conjugate focus with the retina, on which a clear and sharply defined image is formed, and the image of this image, formed by the dioptric apparatus of the eye, which is the one we see, is also bright, with sharp edges. Now as the retina moves backward or forward from this position of conjugate focus (the mirror remaining in the same position)—that is to say, as the eye becomes hyperopic or myopic, the retinal image becomes larger in extent, but less bright and with more blurred outline, the same amount of light covering a larger area.

It should also be remembered, in this connection, that

[1] The Refraction of the Eye. By Gustavus Hartridge. Third edition. Philadelphia: P. Blakiston Son & Co., 1888.

[2] Traité des Maladies des Yeux. Par Dr. X. Galezowski. Third edition. Paris: J. B. Ballière, 1888.

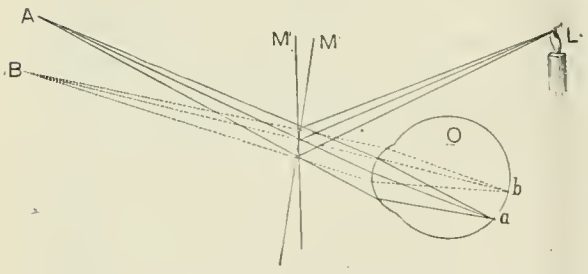
[3] Schmidt Rimpler's plan of determining refraction by the indirect method of ophthalmoscopic examination has its basis on this principle.

the size of the pupil controlling, as it does, the amount of light entering the eye (in fact, the retinal bright area is, to a degree, an image of the pupil) has much to do with the brightness of the image, as does also the amount of pigment at the part of the fundus on which the illuminated area is formed. There are so many factors entering into the production of the brightness of the image, which, after all, is only relative, that we cannot attach much signification to it as a diagnostic sign and can only say that as the retina and the source of illumination depart from the positions of conjugate foci, the retinal illuminated area becomes, *pari passu*, blurred in outline, and, of course, if its outline is blurred, the outline of its image must be proportionately blurred.

EXAMINATION WITH THE PLANE MIRROR.

The chief differences in the use of the concave and plane mirrors in making the "shadow-test" consist in changes in the position of the source of illumination and in the relations of the movement of the mirror and the shadow. The causes of this difference will be apparent at once on an examination of Fig. 4. The light diverging from the flame L behind the eye and falling upon the plane mirror M will be reflected and assume a direction as if it came from A, situated the same distance behind the mirror as L is in the front of it, A thus becoming the real source of illumination. These rays entering the eye O will form the illuminated area *a*. When the mirror is rotated to the position M′, in accordance with the same law, B becomes the source of illumination and forms the retinal bright area at *b*.

Fig. 4.



The relation of these movements to each other, it will be observed, are the opposite of those we found when using the concave mirror. There the source of illumination moved in the same direction with the mirror, here in the opposite direction; there the bright area on the fundus moved in the opposite direction to the mirror, here in the same direction. This necessarily entails a difference in the relative movements of the mirror and of the image of the retinal bright area, with its shadowy edge formed by the optical apparatus of the eye, and which we observe for diagnostic purposes. This image of the retinal bright area is always found on a line passing through the centre of the bright area and the nodal point of the eye, as shown in Fig. 1, and the same law, in this particular, applies to both methods, but it is apparent at a glance that those images formed *in front* of the mirror, between the observed eye and the mirror M, move *against* the mirror, while those formed behind the mirror (weak M.), and at infinity (E), and behind the eye (H), must move *with* the mirror.

The law regarding the *rate of movement* is the same here as with the use of the concave mirror.

As regards the *brightness* of the area and the sharpness of the shadow edge, what has been said under the head of the concave mirror applies here. It is apparent, however, that since the source of illumination is always behind the mirror, we can never have even one point where the brightness is as intense and the shadow so sharply defined as we can have it in some degrees of myopia with the other method, and for the simple reason that the conjugate focus of the retina and source of illumination, are never in front of the eye of the observer.

Recapitulating, then, the shadow phenomena with a plane mirror, we have:

1. Movement of shadow *with* the mirror—E., H. or weak M.

2. Movement *against* the mirror—M with its far-point between the observed and the observing eye.

3. The slower the movement the greater the degree of ametropia (M. or H.).

As regards the relative merits of the two methods, there exists quite a difference of opinion among those practising them. There is, however, one advantage connected with the use of the plane mirror, which has caused me to give it a preference over the concave in the usual routine examinations. Unless the concave mirror has a very long focus—longer than that of the mirrors of our ordinary ophthalmoscopes—it is necessary to keep comparatively close to the observed eye—certainly not farther away than sixty inches—in order to have sufficient illumination. If we get farther away than this, the cone of light becomes so large by the time it reaches the face that the manipulation of the mirror is rendered somewhat difficult and the illuminated area on the fundus so faint as to be almost indistinguishable, particularly if the eyes are dark. This makes it impossible accurately to detect myopia weaker than 0.75 D. With the plane mirror, however, the farther you get away from the eye under examination (within certain limits) the smaller the light area on the face becomes until the rays reflected from it become essentially parallel. This last point is reached when the distance from the mirror to the light is about one hundred inches. It is possible, with the plane mirror, to get from one hundred and twenty to one hundred and sixty inches from the observed eye, and have a fairly good illumination, and thus measure 0.25 D. of myopia if necessary.

Another reason for the more general use of the plane mirror, in this country at least, is that the concave mirrors on most of the ophthalmoscopes in use here are "tilting" segmental mirrors, ill-fitted for this method of examination. Besides, a plane mirror is very useful for other ophthalmoscopic purposes, and you should always have one on hand. I have combined the "tilting" and plane mirrors in my own ophthalmoscope[1] in a very convenient manner, by having the tilting concave mirror swung in front of the plane one. The plane mirror does not interfere in the least with the concave mirror when the latter is in use, and when it is desired to use the plane mirror alone, the tilting mirror can be detached in a second from its upper bearing and fastened below, leaving the plane mirror free. After a constant use of this

[1] Manufactured by Queen & Co., Philadelphia. For description see Trans. Amer. Oph. Soc., 1887.

instrument for over a year, I have every reason to be satisfied with the arrangement.

Up to this point, however, we have been able to tell only the kind, but not the *degree of ametropia*, except, in a general way, by the amount of shadow movement compared with what we know it to be in emmetropia. This is by no means sufficient for accurate diagnostic purposes. The simplest as well as the best means of accomplishing this is to place in front of the eye, under examination, glasses of a kind to correct the faulty refraction that is present, one after another, until one is found that gives an emmetropic shadow movement. For example: Suppose the examination is made by means of the concave mirror and at a distance of fifty-three inches (1.33 m.), and that the movement is *with* the mirror and rather slow as compared with the mirror movements. This, we know, is myopia—and at least of medium degree. We then put in the trial frame a — 3 D. and place it in front of the eye under examination and see what shadow movements we get through this. There is still movement with the mirror, but it is more rapid than before. This shows that there is myopia yet greater than 3 D. We try —4, and still there is movement with the mirror. A — 5 gives very slight movement against the mirror. This shows that the aërial image is formed behind the observing eye. If — 4.75 or — 4.5 give movement with, we may know that the — 5 D. has reduced the M. to about 0.75 — that is, to a myopia having a far-point at fifty-three inches (1.33 m.) from the eye, or near the observing eye. Add this to the — 5, and we have — 5.75 D. as expressive of the myopia of the eye under examination. In other words, find the weakest lens which at a distance of fifty-three inches from the eye gives a reverse movement, then add 0.75 and you have the lens required in myopia.

If it is hypermetropia, of course you must subtract 0.75, for in order to obtain a reversal of movement you have to induce a M. of 0.75 D., and a reversal produced by + 4, for instance, means a H. of 4.25 D., the other 0.75 being required to bring the far-point from infinity to the position of reversal in front of the observer. Of course, if the plane mirror is used, you can get much farther away, as far indeed as one hundred and sixty inches, where an ametropia of 0.25 D. can be measured directly—since the far-point of a myopia of 0.25 D. is at one hundred and sixty inches (4 m.), and where, necessarily, is found the point of reversal of shadow movement.

The disadvantages of the method you see at once to be the consumption of time in placing and replacing the different lenses in the trial frame in front of the eye. To obviate this, to some extent, Mr. Doyne, of Oxford, England, has devised a disk with a flange like the edge of a dinner-plate, in which is fitted a series of lenses. This disk is placed in front of the patient and while the flat surface stands obliquely to the plane of the face the flange with its lenses lies parallel to it and at right angles to the visual axis. The disk, which is about 1½ feet in diameter, standing thus obliquely, can be revolved on its axis in such a way as to bring the lenses successively in front of the eye under examination by a person with an arm of an average length at a distance of about fifty inches.[1]

[1] Since the MS. has been in the hands of the printer I have myself arranged a disk of hard rubber containing 25 lenses, each 3 cm. in diameter, in such a way as to enable the patient to revolve it and bring each one successively, as required, before the eye under examination. The disk can be attached to a stand or fastened by an arm to the wall of the ophthalmoscopic room. I find it to be easily manipulated, and, enabling the observer to get at a greater distance from the patient, is more convenient than the apparatus of Doyne. A graduated tape, attached to the disk, enables the observer to tell exactly his distance from the observed eye.

Another method, first suggested, I believe, by Chibret, but also by Jackson, of Philadelphia, is to move the mirror toward the eye under examination until the point of reversal is found; then the distance from the observed to the observing eye marks the far-point of the eye under examination. This is an excellent method for rapidly detecting, in a rough manner, the degree of myopia; and for other cases an artificial myopia can be induced by means of a convex lens of a known focus. The point of reversal through this lens being found, the strength of the lens is to be subtracted from the myopia thus manifested.

If, for example, we use a + 5 D. with a focus of 20 cm. (eight inches) $\left(\frac{100}{XX} = 5\right)$ and we find the point of reversal at 20 cm., we know there is emmetropia (5—5= 0). If the point of reversal is at 33 cm. (thirteen inches), we have $5-\left(\frac{100}{XXXIII} =\right)3 = 2$ D. of hypermetropia; if at 50 cm. (twenty inches), $5-\left(\frac{100}{L} =\right)2 = 3$ D. of H., and so on. If there is H. higher than 5 D., we must use a + 8 D. or even + 10 D. in the trial frame.

THE DETERMINATION OF ASTIGMATISM.

Probably the most valuable application of the shadow test is to the unravelling of the tangled and complicated threads of evidence which so often present themselves in determining astigmatism. A few movements of the mirror are often sufficient to fix the character of an astigmatism, concerning which a tedious examination with glasses failed to give any satisfactory knowledge.

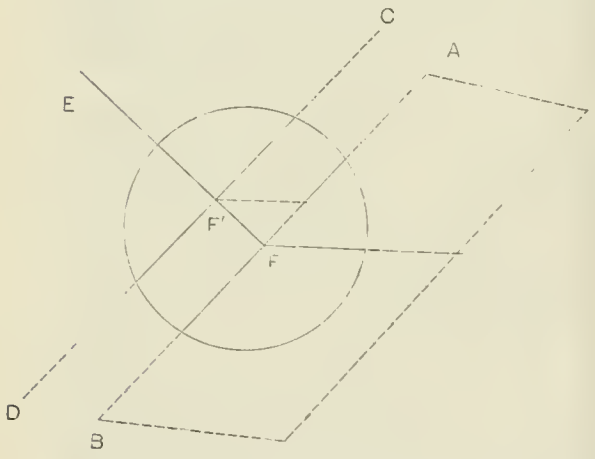
The ease with which this is done is readily understood when we remember that astigmatism is only a difference in the refraction of the opposing meridians of the eye and that we can, by changing the axis of rotation of the mirror, test successively the refraction of each separate meridian. We are further assisted, moreover, in determining astigmatism by some peculiarities of shadow-movement due entirely to the astigmatic refraction.

In testing for astigmatism we follow the same general plan as for general ametropia, the only difference being that we do not limit the rotation of the mirror to one direction. We rotate first horizontally then vertically, and if the shadow movements are of the same character and degree and particularly if the edge of the shadow always moves strictly in the direction of the mirror movement (with or against), we may know that no astigmatism exists. If, however, we find a difference either of kind or amount of shadow movement in the opposing meridians, or that the shadow edge moves obliquely to the mirror movement, astigmatism certainly is present.

The obliquity of shadow movement is not only valuable in giving us knowledge of the existence of astigmatism, but especially in showing us the direction of the faulty meridian. The reasons for this are as follows:

In our studies of astigmatism we found that the image of a point, or circular area of light formed by an astigmatic system, was not a point but a series of ellipses whose axes coincided with the greatest and least refracting meridians. Now, the image of the light spot on the fundus, formed by the astigmatic refracting media of the eye, is likewise an ellipse with its axes corresponding to the meridians of least and greatest refraction. Moreover, the ellipse is so large that the small part of it that is seen by the observer passing across the pupil space appears almost straight, as, indeed, does the edges of the circular image in the non-astigmatic eye. When, however, there is an obliquity of the axis of the faulty meridian, and the mirror is rotated horizontally, we will say, the shadow does not appear to pass horizontally across the pupil, but in a direction at right angles to the axis of ellipse. You can demonstrate this experimentally by holding a body with the straight edge behind a round opening in a board, as A B Fig. 5, and moving it horizontally to C D. Although the movement may have been strictly horizontal, the apparent movement, as seen through the opening, will be in the direction of E, at right angles to the edge. So you have only to make the rotations of the mirror horizontally and vertically and the direction in which the edge of the shadow moves will indicate the direction of the faulty meridian.

FIG. 5.



To determine the amount of astigmatism, the same plan precisely is to be followed as in the determination of general ametropia—that is, we work out the refraction in each meridian separately with spherical lenses or by finding the point of reversal of movement, in the manner already indicated. In these examinations of each separate meridian we should always make the rotation of the mirror strictly at right angles to its axis and in the direction of the shadow movement, otherwise there are likely to be confusion and error, particularly when one meridian is at or near 45°.

When the kind and degree of the astigmatism have been thus determined, a cylinder suitable for the correction is placed in the frame with the axis in the direction indicated in the examination. The shadow movement should then be the same on rotation of the mirror in all directions; and when there is general ametropia present (compound astigmatism), the addition of the correcting spherical lens should give emmetropic movements.

A few general observations and we are done. The examination is somewhat easier when the pupil is large, but the necessity for a mydriatic is felt far less in this than in the direct ophthalmoscopic method. The flame should be behind and, by preference, above the head of the patient and the face as free as possible from light other than that from the mirror. It has been called a simple method of testing the refraction, and so it is; but simple as it is, it cannot be mastered without painstaking care as to the smaller details; and considerable experience is necessary before it can be executed with the rapidity and certainty of which it is capable, and which are among its recommendations to the practitioner. It will not supplant all other means of determining refraction, but it is certainly scientific, as we trust we have shown, and by care and patient practice can be made as reliable as any.

ORIGINAL ARTICLES.

THE POISONOUS EFFECTS OF CIGARETTE-SMOKING.

BY WILLIAM L. DUDLEY, M.D.,
PROFESSOR OF CHEMISTRY IN THE VANDERBILT UNIVERSITY, NASHVILLE, TENN.

THE fact that cigarette-smoking produces physiological effects differing to some extent from those of the cigar has led me to make the experiments which I record here, tending toward an explanation of it. The frequently ascribed cause of the difference: that of the adulteration of cigarrette tobacco with opium and other drugs and also the presence of arsenic in the paper are for many reasons unsatisfactory and insufficient. It is true, no doubt, that the tobacco in many of the less expensive brands is adulterated with cheap drugs and artificial flavors and that in the more expensive grades opium may be used; but I believe it to be equally true that many cigarettes are made of tobacco which is free from sophistication. The presence of arsenic in the paper is entirely out of the question.

Before describing the experiments in detail, I shall discuss "smoking" in general. In "smoking" it is, of course, necessary that the tobacco should undergo combustion to a greater or less degree. The principal elements found in tobacco are carbon, hydrogen, nitrogen and oxygen, and, of these, the carbon and hydrogen are combustible, while the nitrogen and oxygen are non-combustible.

Besides combustion, destructive distillation takes place in the pipe, cigar or cigarette, as the result of the heat and the exclusion of the oxygen of the air which has been completely used up in passing through the red-hot burning tobacco, in front of that which the fire has not yet reached. The products of this destructive distillation are ammonia, a yellow and very poisonous substance of disagreeable odor, called nicotianine, some nicotine (but most of

the latter has been destroyed by the heat) and many other products of minor importance.

The result of the combustion of the hydrogen referred to previously is water; and the products of the combustion of the carbon are carbonic acid gas, or carbon dioxide, and carbonic oxide, or carbon monoxide. Carbon dioxide is the result of the complete combustion of carbon, and carbon monoxide is the result of the semi-combustion of carbon.

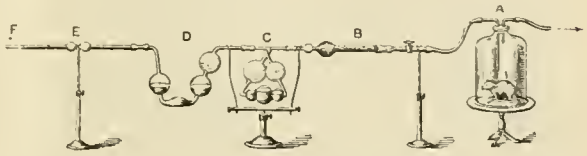
What is known, then, as tobacco smoke is a mixture of the products of combustion and of destructive distillation of the tobacco with the nitrogen of the air. The products of the combustion of the carbon predominate, if measured by volume, and of these carbon monoxide is in excess of carbon dioxide for the following reason: When carbon is burned in an excess of oxygen the result is carbon dioxide, and when this carbon dioxide comes in contact with red-hot carbon it is deoxidized and carbon monoxide is formed. This is seen in the combustion of charcoal, coke or anthracite in a grate or stove; the air passes through the grate bars and comes in contact with the red-hot carbon and carbon dioxide is formed: this gas is impelled by the draught to pass through the bed of glowing coals, and, in so doing, it is reduced to carbon monoxide, which, when it reaches the top, encounters a draught of air and burns with a pale blue, lambent flame, becoming oxidized to carbon dioxide again. This is similar to what takes place at the end of a cigar or cigarette or in a pipe, where there is a layer of fire from $\frac{1}{64}$ to $\frac{1}{16}$ of an inch in thickness, and as the air is drawn through it, carbon dioxide is first formed; on passing through the hot carbon this is reduced to carbon monoxide, and, as such, it is drawn into the mouth, for when it passes beyond the fire there is no air or oxygen to convert it back to carbon dioxide.

Now let us consider the properties of these products of the combustion of carbon: carbon dioxide will neither burn nor support combustion. It fails to support life, but is not poisonous; it simply produces death by suffocation. On the other hand, carbon monoxide does not support combustion, but burns with a pale blue flame. It fails to support life because it is extremely poisonous, and this is due to the affinity which it has for the hemoglobin of the blood. It has the power to expel all of the dissolved and loosely combined oxygen from the blood, and it converts the oxyhemoglobin into carbonic-oxide-hemoglobin, which, of course, results in death. The blood thus affected acquires a florid arterial hue, which differs from the normal color of the blood by its persistence. An animal plunged into an atmosphere of carbonic oxide, dies instantly, and, when small quantities mixed with air are breathed, headache, giddiness and insensibility readily occur. Death from carbonic oxide is easily proved by a spectroscopic examination of the blood of the victim.

There is a difference in the methods of smoking a cigarette and a cigar or pipe. In the two last-mentioned, the smoke is simply drawn into the mouth and expelled directly therefrom or through the nose, while the experienced cigarette-smoker will inhale the smoke—that is, draw it to a greater or less extent into the air-passages and in some cases to the greatest depth of the lungs, and thus the absorption of the carbonic oxide and other gases will take place very rapidly, causing more or less deoxidation of the blood and thereby impairing its power to build up the wasting tissues of the body.

Acting upon this theory I proceeded to experiment on animals and obtained for the purpose some mice. The animal to be experimented with was placed in a glass bell-jar, into which the smoke of a cigarette mixed with air could be drawn as rapidly as desired by means of a laboratory aspirator.

In the first experiment the smoke was purified as much as possible, and the atmosphere breathed by the animal was practically oxygen, nitrogen and carbonic oxide. The apparatus employed is shown in the accompanying figure.



The cigarette F was loosely inserted in the end of the tube E having two bulbs. D and C are bulbs containing a solution of potassium hydrate to absorb the carbon dioxide and any acids or condensable bodies not deposited in E. B is a tube containing solid potassium hydrate broken into small lumps, which retained any carbon dioxide that may have escaped the bulbs C and D. The animal was placed in the bell-jar and the apparatus connected together as shown in the figure. The aspirator, which was connected with the rubber tube leading from A, was turned on so as to draw a slow current of air through the apparatus in the direction indicated by the arrow. The cigarette was then lighted and in twenty-two minutes the animal was dead.

On examination of the blood of the animal by the spectroscope it was found that all of the oxyhemoglobin had been converted into carbonic-oxide-hemoglobin, which showed that carbonic oxide was the cause of the death. This experiment was repeated and the result was the same; the animal died in twenty-five minutes, and the spectroscope revealed the same condition of the blood.

A third experiment was made without the bulbs C and D and the tube B. The tube E, carrying the cigarette F, was connected directly to A, and thus

the smoke was drawn into the bell-jar without the removal of any of its original constituents. In this case the animal died in six minutes, and the examination again showed that the carbonic oxide was the immediate cause of death, proving that it was the most noxious constituent of the tobacco smoke. The time required to produce death in the last experiment was about one-fourth that required in the first and second. This was probably due to the fact that in the latter the smoking was done more rapidly than in the preceding, owing to the lessened resistance in the apparatus and the difficulty encountered in reducing the force of the aspirator. In each case, however, the amount smoked up to the time of death was about the same, one and one-fourth cigarettes.

From these experiments I feel justified in drawing the following conclusions:

1. That carbonic oxide is the most poisonous constituent of tobacco smoke.

2. That more injury results from cigarette than cigar- or pipe-smoking, because, as a rule, the smoke of the former is inhaled.

3. That cigarette smoking without inhaling is no more injurious than pipe- or cigar-smoking.

4. That the smoke of a cigar or pipe, if inhaled, is as injurious as cigarette smoke inhaled.

5. That the smoke from a Turkish pipe, if inhaled, is as injurious as that of a cigarette inhaled.

In these experiments I was ably assisted by Mr. W. J. Pulley, who was at the time doing special work in physiological chemistry under my direction.

THE NATURE OF THE ROTATION WHICH THE HEART UNDERGOES IN ACQUIRED DEXIOCARDIA, AS SHOWN BY THE AUTOPSIES IN TWO CASES.

BY ROBERT H. BABCOCK, A.M., M.D.,
PROFESSOR OF DISEASES OF THE CHEST AND PHYSICAL DIAGNOSIS IN THE CHICAGO POLYCLINIC; PHYSICIAN TO THE THROAT AND CHEST DEPARTMENT OF THE SOUTHSIDE FREE DISPENSARY, CHICAGO, ILLINOIS.

LATERAL displacement of the heart is of interest chiefly to the pathological anatomist, and from the standpoint of diagnosis. Its bearing upon the therapeutic measures employed in any case in which it occurs is too slight to be here considered. Neither is it desirable to review the literature of the subject at length, inasmuch as it is coextensive with that of diseases of the heart and lungs. Following in the footsteps of Stokes, all writers on diseases of the chest have discussed at greater or less length the various displacements which the heart may undergo as a result of abnormal conditions of the pleuræ or lungs as well as of itself and its great vessels. Of the many changes in position to which the heart may be subjected, it is the displacement to either side, and, again, that to the right, known as dexiocardia, which have aroused the greatest interest. There are several reasons for this: 1. The pulsation of the heart in the right side of the chest is a more startling deviation from nature than any displacement that still keeps the organ to the left of the sternum. It early arrests the patient's attention and excites his apprehension, while it is hardly possible to be overlooked by the physician even without the aid of a careful physical examination. 2. Cardiac displacements to the right or left are the results of intrathoracic affections of such severity as to concentrate the attention upon the chest, and they take place with greater rapidity than those in which change of position accompanies a lesion of the heart itself or its supports. 3. Transposition of the heart to the right of the sternum not only constitutes a phenomenon readily discoverable from without, but necessitates grave alteration in the anatomy of the parts, in consequence of which it would seem that profound functional disturbance must be inevitable. It is not difficult to understand, therefore, why of all cardiac displacements dexiocardia should awaken the deepest interest.

The chief causes of acquired dexiocardia are: 1, effusion of air or liquid into the left pleural cavity by which the heart is pushed over into the opposite side; 2, inflammation of the right lung with its investing membranes, which leads to their adhesion with the pericardium, and, through subsequent contraction, to the drawing of the heart to the right of the median line. As might be expected, conditions that exercise traction upon the heart operate more powerfully than such as push it out of position toward the right. In cases of left-sided effusion sufficient to crowd the heart beyond the median line, the organ is generally seen to pulsate in the neighborhood of the right nipple, somewhat to the inner side and "between the fifth and seventh ribs."[1] The effusion is rarely so great as to push the heart's apex to the outer side of the right mammary line. Hence the organ comes to occupy a position on the right side almost identical with that it formerly held on the left. In such cases, too, the transposition may take place with remarkable rapidity. Thus Walshe observes: "In cases of left effusion the organ may pulsate outside the right nipple, and thirty-six hours will sometimes suffice to produce this amount of malposition."[2]

When the dexiocardia is owing to traction through the shrinkage of pleuro-pericardial adhesions with, at the same time, cirrhosis of the lung, the heart may come to lie wholly to the right of the sternum. "Dr. Greenhow[3] gives a case of contraction of the right lung, the precise condition of which was un-

known, observed by him during life, in which the heart was displaced very far to the right and upward, and was felt beating in the third and fourth spaces over an area of three inches by three inches and a half, of which the right nipple formed the central point."[1]

I have reported a case[2] of cirrhosis of the right lung in which the heart occupied a transverse position wholly to the right of the sternum. It formed a pulsating prominence extending from a line three inches below the clavicle to the upper boundary of hepatic dulness and from the right border of the sternum to a point two and three-fifths inches outside of the nipple, a transverse distance of five and a half inches.

That the heart can become so extensively displaced without serious interference with its function is not the least remarkable fact associated with this condition, for whatever disturbance of the general health is manifested appears to me to be the result not so much of the change in the position of the heart as of the concomitant disease of the lung or pleura. *Apropos* of this Schroetter remarks: "The change in the position of the heart as such, as a rule, occasions no functional disturbance. The more extreme displacements, however, may, from interfering with the normal contractile power of the heart or insufficient filling of its cavities, give rise to a tendency to stasis and its results."[3]

Whether any change in the cardiac sounds, and, if so, what change may be produced by these dislocations, is a question of considerable interest. Relative hereto Stokes observes: "The experience of upward of twenty cases has convinced me that this dislocation of the heart, even when at its greatest degree, does not cause any alteration in the natural sounds of the organ; indeed, it is singular how little its action is excited in many of these cases."[4] In this respect Walshe[5] asserts that his experience accords with that of Stokes. Hope, on the other hand, cites one of his cases in which murmurs were heard with the first sound, and queries, "Is it, therefore, possible that a twist given to the aorta, or pressure of the vessel against the ribs, may be the cause of a murmur under such circumstances?"[6] Schroetter coincides with Hope in the opinion that adventitious sounds may be generated by the twisting or bending of the great vessels. He says, "in such cases murmurs may be developed over the great vessels which simulate lesions of the valves."[7] He cites a case of great displacement of the heart to the left and downward, from pleuritic effusion, in which he heard a systolic murmur during life, but was not able to discover any lesion of the valves after death, and hence concluded that the murmur had been due to stretching of the aorta. In my case cited above there was a systolic bellows murmur heard most distinctly at a point two inches above the right nipple, while at the same spot the second sound became distinctly reduplicated. Nearer the sternum the murmur was lost, the first sound was impure and the highly accentuated second appeared at times to merge into a short, rough bruit. As will be seen later on, in the description of my two other cases, murmurs were likewise audible. Unquestionably, in many cases, murmurs may exist which depend upon an alteration in the quality of the blood rather than any distortion of the heart or large vessels. Nevertheless a moment's reflection upon the probable mode of production of blood murmurs makes it appear hardly possible for an acquired dexiocardia to exist without the development of murmurs. More or less change from the normal configuration of the heart and great vessels is almost inevitable and hence gives rise to conditions favorable to the production of fluid veins—that is, sonorous vibrations within the blood stream. Moreover, it is not impossible for compression or twisting of the organ so to alter the shape of the *ostia* as to render the respective valves relatively incompetent.

Such conjectures are interesting, but the subject of chief concern relates to the deviations from their natural configuration which the parts present *post-mortem*. Were the apex and body of the heart no more movable than the base, the organ would necessarily be moved over toward the right *en masse* while still keeping its relative position to the long axis of the thorax. As it is, to quote the words of Sibson, "the apex forms throughout the lowest part of the heart, and it describes a segment of a circle or arc as it sweeps round from its natural position in the left side of the chest to the position of extreme deviation to which it may attain in the right side of the chest."[1] To enable the apex to make so extensive an excursion, the body of the organ has to undergo rotation upon its long axis, and it is in thus revolving that a twist is likely to occur. Most authors do not describe the manner in which the organ rotates. Sibson, however, whom contemporaneous English writers appear to accept as authority on the subject, discusses at some length the mode of rotation occasioned by lateral displacement. He illustrates by diagrams the state of things found by him in several cases. He says, "as the heart passes over from the left to the right side of the chest it gradually and necessarily turns over upon itself, hinging, so to speak, upon the vessels by which the heart is attached

to the lungs and the system, so that the right auricle is hidden, all but the top of its appendix, and instead of the right ventricle being in front of the left ventricle, all but its left border, it is the reverse, for the left ventricle hides a large portion of the right ventricle. The part of the right ventricle exposed is, however, not that near the apex, but near the pulmonary artery. The ascending aorta and pulmonary artery change their direction; they move to the right at their respective origins, but higher up they are retained in their places, the arch of the aorta at the end of its transverse portion, and the pulmonary artery at its bifurcation. The aorta and pulmonary artery, therefore, present not a front but a profile view, with a direction to the right."[1]

Concerning the cardiac revolution in these cases, the following is expressed by J. Mitchell Bruce:

"The tendency that the heart has to rotate or roll on one or the other of its axes is also affected by its attachments at the root. If the heart lay free in the pericardial cavity, there would be no limit to such rotation under the influence of pressure or traction. The base being fixed, rotation is greatly limited and does not occur to any extent except around the longitudinal axis; the left ventricle, for example, being rotated more forward or more backward as the case may be. Rotation around the transverse horizontal and the antero-posterior axis is very limited."[2]

From the foregoing it would seem that Sibson considers the rotation likely to take place in such a manner as to bring the left ventricle to the front; while Bruce contents himself with the statement that the left ventricle may roll either forward or backward.

Schroetter, on the other hand, expresses himself rather more positively when he says, "turning of the heart on its long axis generally occurs in such a manner that the right auricle and ventricle come to look more directly forward and the left cavities backward." "Bamberger relates a case of pneumothorax on the left side, in which the heart was not only pushed over to the right, as is usual, but had so revolved on its long axis that the greater portion of the left ventricle looked forward. This revolution was so considerable that torsion of both the great vessels could be easily recognized. It is hard to picture to one's self how this came to pass, inasmuch as there were no contracting bands found here, and it may be that, with an original tendency of the heart in that direction, a weak spot in its suspension gave occasion to the displacement and torsion."[3]

If the anatomy of the great arteries be considered, it would seem as if the heart could not well rotate in any other manner than as described by Schroetter —*i. e.*, from right to left backward. Were rotation of the entire organ to take place in the opposite direction—that is, from behind forward and from left to right—it would cause the pulmonary artery and its right branch to be wound tightly about the base of the aorta, thus greatly constricting its lumen. Fortunately the firm fixation of the base of the heart prevents this, and, as shown by my Case II., the rotation in this direction is achieved by a twist in the body of the heart. Doubtless, as intimated by Schroetter, in cases of dexiocardia due to pressure and without adhesions, rotation is more easily accomplished in the direction he describes. Yet, Sibson's Diagram 76, illustrating the rotation of the left ventricle in front of the right, represents what occurs in cases of left pleuritic effusion.

Case I.—Walter F., æt. three years and four months, Irish, was first seen and examined by me May 21, 1884. There was history of some sort of intrathoracic disease during the first few weeks of life. He was extremely delicate up to his second year and always very prone to colds and coughs.

Status præsens.—Is fairly nourished; plays with other children, but is peevish and backward in mental devolopment; appetite capricious and bowels inclined to be too relaxed; has a loose cough and gets blue in the face when playing or running.

Inspection.—Pupils normal, slight cyanosis of the face and congestion of the veins of the chest, chiefly on left side; flattening of the anterior surface of left thorax, most marked in submammary region; a pulsating area at right of sternum, pulsation seen in third, fourth and fifth spaces; flattening of the latero-posterior and inferior aspect of right side of chest; epigastric pulsation.

Palpation.—Cardiac impulse diffused and apex-beat in fifth space below right nipple, not very forcible; pulse rapid, weak, regular, rate not counted.

Mensuration.—Left side at level of second rib, 26 centimetres and at fifth rib 24.9 centimetres, while on right side at corresponding levels the measurements are 28 centimetres and 27 centimetres respectively.

Percussion —The note is resonant over left side, specially full at posterior base; no cardiac dulness at left of sternum, but beginning at its left edge above, an area of flatness passes downward and outward to the outer side of the right nipple. From this point the percussion note shades gradually off into faint resonance behind.

Auscultation.—Exaggerated puerile respiration throughout left side, with rhonchi at base. Upon right side posteriorly very feeble bronchial breath-sounds, and at base laterally dry friction sounds. The heart's sounds are loud, and the first somewhat obscured by a systolic murmur most distinct at apex but audible throughout the præcordia. This murmur seems composed of two, a short, low, harsh bruit that merges into a high-pitched bellows-like whiff at close of systole. The second sound is greatly accented, prolonged and impure.

Diagnosis.—Acquired dexiocardia; compression of right lung; old pleuritic adhesions of right side: secondary chronic bronchitis of left lung; possibly old adhesions of the left pleuræ.

[1] Op. cit., p. 445.
[2] Dictionary of Medicine, Quain, Amer. ed., p. 591.
[3] Op. cit., p. 177.

During the ensuing summer the little patient remained in fair health, but as winter approached his cough and expectoration increased, appetite failed, strength waned and in spite of appropriate treatment he died January 14, 1885, of broncho-pneumonia.

Only a partial *post-mortem* examination was permitted by the family in the presence of the father, and hence it was impossible to obtain the thoracic organs. The autopsy was conducted by Dr. F. C. Schaefer, Professor of Anatomy at Chicago Medical College, in the presence of Dr. W. W. Jaggard, a student and myself.

The following is the report, together with the illustration, as kindly furnished by Dr. Schaefer. The autopsy took place sixteen hours after death.

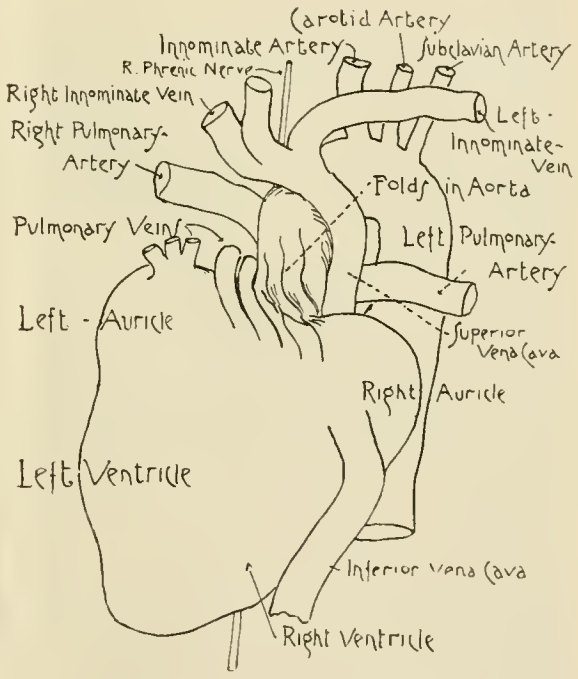
The right innominate vein was adherent to the second costal cartilage and extended partly across the anterior surface of the aortic arch toward the left side having been carried over by the rotation of the heart from right to left, forward. The pericardium was attached to the right half of the sternum and to the corresponding right costal cartilages: also to the rib surfaces about one inch to the right of the cartilages. The right lung was crowded back into the fossa between the bodies of the vertebræ and the ribs, and was almost completely collapsed. The apex of the heart pointed an inch higher on the right side than the usual position on the left side. The extreme left boundary of the pericardium was *two* inches to the left of the median line, while the extreme right boundary was placed at the distance of three and one-half inches to the right of the median line. Upon opening the pericardium a small quantity of serum escaped from the sac, and fresh deposits of lymph were visible upon the heart's surface. The sac was unusually large. The first section of the aortic arch joined the second section at an obtuse angle, owing to the elevated position of the heart. The right ventricle presented to the front. The posterior surface of the right auricle could be seen in front and to the left, its anterior surface having been turned back looking toward the vertebræ. The left auricle, twisted upon its vertical axis, came partly into view in front and to the right. The inferior vena cava also twisted upon itself, from right to left, was visible in front, near the left side of the heart (Fig. 1). The right pulmonary artery was on a plane superior and posterior to that of the left one. The pulmonary veins were greatly stretched,—the right one was almost tense. The three large branches of the aortic arch were in the normal position. The heart was enlarged a little more than one-half and twisted upon its vertical axis from behind forward, and from right to left. Distinct folds existed in the first section of the aortic arch. These folds were almost vertical in direction, and were obliterated by rotating the heart in the reverse direction. This portion of the aortic arch was dilated to the extent of two diameters, and its walls were very thin. At the junction of the first and second sections of the aortic arch there existed a firm, cord-like annular constriction almost completely surrounding the vessel. This ring-like band was formed by the superior vena cava and the right innominate vein; these vessels having accompanied the right auricle in its rotation; the extent of this rotation having been so great as to cause the anterior surface of the right auricle to look backward, thus crowding the superior vena cava under the arch of the aorta; the right innominate vein joining the superior vena cava in front of the aorta as represented in Fig. 1.

The left innominate vein was folded back just before it joined the right vein to form the superior vena cava. The right phrenic nerve descended behind the heart.

The auricles were a trifle enlarged and very irregular in outline, being curved upon their vertical axes. Both ventricles were enlarged, the right one about one-third; the left one to about three times the normal size. Its walls were about half the usual thickness. This great increase in size of the left ventricle was doubtless caused by the resistance occasioned by the constriction of the aortic arch. (Fig. 1.)

There can be no doubt about the direction of rotation in this case. The anatomical relations of the various parts connected with the heart indicate it too plainly to admit of a wrong interpretation. (Fig. 1.)

FIG. 1.



CASE II.—George E., æt. eighteen years. American, was seen for the only time March 31, 1885. History: His older brother died of consumption a year or two ago. Patient has been ill for over a year, and during the summer of 1884 was so ill with some intrathoracic inflammation that he only recovered with difficulty and slowness. Since then he has noticed that his heart beats on the right side. *Status præsens.* Symptoms: profound weakness, anorexia and diarrhœa, daily fever, annoying cough with but slight expectoration. Inspection: patient sits propped up in an easy chair, is extremely weak

and emaciated, phthisical habitus marked, and breathing so superficial as to cause scarcely perceptible movements of the chest. Cardiac impulse visible just below the right nipple. Pulse 124, very feeble, and respirations 38.

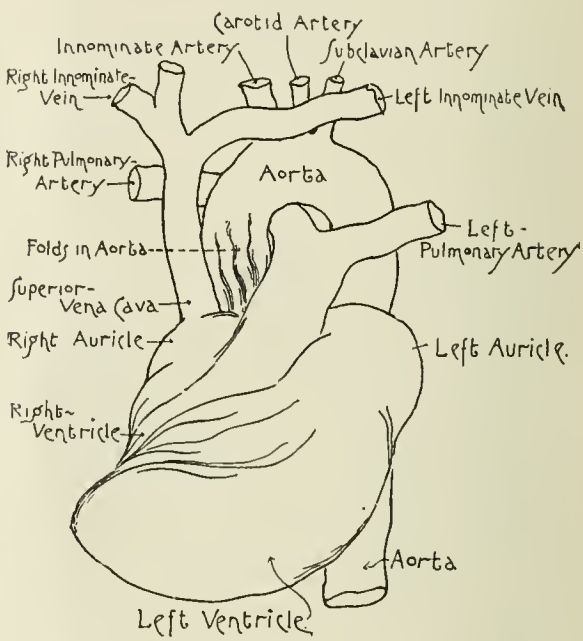
Owing to the prostration of the patient only a partial, hasty physical examination could be made and my notes are very meagre, as follows: Percussion: from junction of second costal cartilage with right border of sternum a line of dulness runs obliquely downward and outward to half an inch outside of right nipple, thence passes along the lower border of the fourth rib to the sternum, and from this point upward obliquely to the junction of the left second costal cartilage with the sternum, and thence across this bone to the starting point. The upper margin of hepatic flatness is at the upper border of the sixth rib. Percussion note over the balance of this half of the thorax is faintly resonant, but not so much so as over left lung, where it is hyper-resonant and tympanitic, very drum-like. Auscultation: over right lung, posteriorly, respiration is bronchial and voice bronchophonic and râles of indefinite character. Heart sounds are accented and a systolic bellows murmur accompanies the first over the body of the heart.

During the hasty exploration of the right half of the chest just recorded I made two or three percussion strokes below the left clavicle to compare its note with that of the right and elicited the highly resonant, tympanitic note mentioned. Upon finishing with the right side I prepared to examine the left, but was obliged to desist because of the extreme fatigue of the patient. This was a matter for regret at the time and still more in the light of the *post-mortem* revelation.

The diagnosis was tubercular phthisis in the last stage, dexiocardia as a result of previous pleuritis and contraction of the right lung.

I did not again see the patient during his life, but June 27th was informed of his death two days previous. The consent of the family was obtained to a *post-mortem* examination which, as the funeral was to take place in two hours, had to be hurried and incomplete. It was not possible to obtain any specimens. Dr. W. W. Jaggard kindly conducted the autopsy, assisted by Dr. Charles Caldwell; a student and myself were also present. Necropsy: external appearance not noted because of too great *post-mortem* changes. The chest having been opened —pleuritic adhesions very firm on both sides and separated with difficulty. The pericardium contains no fluid, but is firmly adherent to the heart. Miliary tubercles on both its visceral and parietal layers, most numerous at the base. The left half of the thorax is converted into a complete cavity, no lung tissue found, but the cavity is lined by a cheesy material closely resembling pus. About a pint of pus found at bottom of the cavity. All the bronchi leading into this cavity are occluded. The right lung is crowded back, infiltrated with tubercles and displays numerous calcareous deposits. The heart lies with its left border near the middle of the sternum and is rotated from left to right forward, so that the left ventricle is in front. The apex is at the right of the sternum. The pulmonary artery runs up from the middle of the sternum toward the left, covering the aorta. The aorta is twisted on its axis about ninety degrees backward. The superior vena cava lies to the right and behind the aorta. The inferior vena cava is slightly twisted backward to the left. Both ventricles are thin-walled and dilated. There is a double twisting of the heart, both on its long and transverse axes. The liver is in its normal position. Owing to limited time the abdominal cavity is not examined.

FIG. 2.



These two cases are of interest, as showing, conclusively, that the rotation of the heart in acquired dexiocardia may take place in either direction, and that no law can be formulated concerning it. The factor determining the direction of the rotation is the point on the pericardium at which the adhesion between it and the pleura takes place and not anatomical arrangement of the parts. If this be on the posterior aspect well over to the left, the turning will be backward and from right to left; if, on the contrary, the adhesions pull upon the anterior surface, the heart will have its left ventricle drawn to the front.

Whatever be the nature of the rotation, it seems hardly possible for the resulting distortion to exist without the generation of murmurs independent of blood-murmurs. The short rough bruit heard in the case of Walter F. was doubtless thus occasioned.

Concerning this case it only remains to add, it is truly remarkable that the changes induced in the heart and vessels did not terminate the child's life long before. The diagnosis was confirmed in every particular, with the exception of previous pleurisy of

the left side. The evident flattening of this half of the chest anteriorly, which led me to my supposition, was probably caused by atmospheric pressure upon the yielding parietes when the heart was no longer *in situ naturale*.

The second case is interesting and instructive from another standpoint than that of the cardiac changes —that is, as regards the lungs. Evidently the patient had lived for months upon a mere *modicum* of the oxygen which one would suppose even his system would need. This must have been rendered possible only by the extreme anæmia. Not only was but little oxygen conveyed to the tissues, but the limited number of red blood-corpuscles carried too small an amount of carbonic acid to the respiratory centres to occasion any sense of dyspnœa. The second feature of interest was the absolute destruction of the left lung with the occlusion of the bronchi, by which the half of the thorax was converted into a pyopneumo-thorax. Had the strength of the patient permitted a careful examination of the left side, I must have discovered the condition. As it was, I only tapped the left infraclavicular region twice or thrice in the course of the exploration of the opposite side to compare the percussion note, and was struck by the highly tympanitic quality and low pitch of the note obtained. There was no *bruit de pot fêlé* and there could not have been since the obliterated bronchi prevented all communication with the external air. The lowness of the pitch was due to the size of the cavity, which permitted vibrations of a length extraordinary in the human body. Had circumstances permitted, a succussion sound could have been elicited. Not having expected such utter disorganization of the lung, I was astonished and mortified by the revelation of the necropsy. Reflection upon it, however, has convinced me that, as things were, the failure to recognize the condition was excusable.

THE PROTEIDS OF THE URINE, WITH A COMPARISON OF THE TESTS FOR ALBUMIN.[1]

BY FREDERICK G. NOVY, M.S.,
INSTRUCTOR IN HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN.

BEFORE taking up the immediate subject of this paper, I think it will not be amiss to say a few words in regard to the nature of the proteid substances present in the urine. To the average physician the phrase "albumin in the urine" is quite indefinite, or, rather, I should say, too definite, inasmuch as it conveys to him the idea that he is dealing with one individual substance. This, however, is far from being the case, for we know of at least four well-defined proteids that may occur in the urine. Although we do not know anything about the clinical significance of some of these substances, nevertheless, it is important for us to understand something of their nature and relationship, since it is only in this way that we can hope to attain definite knowledge whereby some of the hitherto obscure phases of disease may be rendered clear.

I have just said that the urine may contain at least four proteids. These are: *serum albumin* or albumin proper, *globulin*, *hemi-albumose* and *peptone*. In the ordinary methods of testing for albumin, the first three members may be readily mistaken one for another, and, indeed, this has been rather the rule than the exception.

The most important of these proteids is serum-albumin, and it is this substance which is usually understood when we speak of "albumin" in the urine. As it occurs, however, in this secretion, it it usually accompanied by larger or smaller quantities of globulin, and, in some instances, even peptones may be present. Our ordinary tests for serum-albumin are also responded to by globulin; and, hence, when applied to an albuminous urine, they indicate, as a rule, a greater amount of serum-albumin than that which is actually present. The number of cases in which globulin occurs by itself, without any serum-albumin, is very small. Consequently, when a specimen of urine under examination yields an albumin reaction, we are justified in assuming the presence of serum-albumin, though it should be carefully borne in mind that the presence of globulin will heighten the reaction.

This proteid is identical with the serum-albumin of the blood and, therefore, belongs to the group of native albumins, of which egg-albumen may be considered a typical representative. It is readily soluble in water, but is insoluble in alcohol. Like other proteids, it is soluble in acids and alkalies, yielding corresponding acid and alkali albuminates. It is coagulated by heat and by acids and, furthermore, gives precipitates with most of the alkaloidal reagents.

Just as, in the blood, we have two well-defined proteids — serum-albumin and serum-globulin, so, also, in the urine, do we find, at times, these two bodies accompanying one another. The globulin which occurs in the urine is, without doubt, identical with serum-globulin, or, what is the same thing, paraglobulin. Usually it accompanies serum-albumin, and may be present in almost all varieties of albuminuria, though in variable quantity. According to Hammarsten,[1] it constitutes from 8.13 to 60.24 per cent. of the total proteids in albuminous urine: whilst still more recent observations of MacGuire[2] indicate that globulin can exist in the urine by itself, even without any serum-albumin being

[1] Read before the Calhoun County Medical Association, Battle Creek, Michigan, May 29, 1888.

[1] Neubauer u. Vogel: Harnanalyze, 1881, p. 127.

[2] London Lancet, June, 1886, pp. 1062, 1106.

present. Thus, in three cases of cyclic or functional albuminuria and one of puerperal albuminuria, he found the proteid of the urine to consist solely of globulin. A short time ago I had under observation what appeared to be a case of functional albuminuria. The individual was a student, apparently in good health; indeed, to use his own words, he "never felt better in his life." The urine had a specific gravity of 1024, was acid in reaction and, on standing, yielded a deposit of uric acid. When passed after rising and just before breakfast, the urine contained no albumin, but shortly after breakfast it appeared. Globulin was found to be present, but, unfortunately, I am unable to give the exact figure as to the amount present.

Globulin is an amorphous, pulverulent powder, insoluble in water and alcohol. In the urine it is held in solution, not by the water, but by the salt; and hence, when globulin-containing urine is diluted with water it yields a cloudy precipitate, inasmuch as the salt, owing to the dilution, is no longer capable of holding the globulin in solution. In other words, globulin is soluble in dilute salines, but is insoluble in water or in concentrated salines. From dilute solutions it is precipitated by passing carbonic acid; but a better method for the isolation of globulin is that of Hammarsten.[1] It is based upon the fact that globulin is insoluble in concentrated salines, and is essentially as follows: Finely pulverized magnesium sulphate is added to the neutral or but slightly acid urine in successive portions till complete saturation is reached—that is, to the point when the urine ceases to dissolve any more of the salt, even on prolonged standing. The globulin is thus precipitated, whilst the serum-albumin remains in solution. The precipitate is gathered upon a filter and washed thoroughly with a saturated solution of magnesium sulphate. The globulin can now be dissolved from the precipitate by the aid of a dilute saline solution, and the amount determined by precipitation and subsequent weighing. The albumin can be determined in the combined filtrate and washings by precipitation with heat and nitric acid. The coagulated albumin is collected upon a previously weighed filter paper, then washed, dried and weighed.

Kühne[2] applied the term hemi-albumose to a group of intermediate proteid products which are formed by the action of digestive ferments or boiling acids on various proteids. It, therefore, occupies a middle position between the genuine proteids—as, for instance, serum-albumin and the final products of digestion, namely, peptones. This peculiar substance was first observed by Bence Jones,[3] in the urine of a case of osteomalacia, and since then has frequently been designated as "Bence Jones albumin." Subsequently, Kühne and Chittenden,[1] as well as Salkowski,[2] have contributed extensively to our knowledge of this interesting albuminoid, which, it seems, is invariably present in osteomalacia. Kühne[3] describes the urine in a case of osteomalacia containing hemi-albumose, as follows: It was yellow, clouded, strongly acid and had a sediment of uric acid, sodium urate, mucous corpuscles and amorphous granules; on shaking, it foamed like soap, but it filtered clear.

The chemical behavior of hemi-albumose is quite peculiar and at the same time distinctive from that of the other proteids that may occur in urine. Thus, when warmed, it yields a heavy, flocculent precipitate, which, as soon as the temperature approaches the boiling-point, redissolves and the solution again becomes clear; but, on cooling, the precipitate reappears. The addition of nitric acid produces a heavy white precipitate, which, when the acid is added in slight excess, redissolves and does not separate on boiling and subsequent cooling. When the acid is added in quantity insufficient to dissolve the precipitate and the liquid is then warmed, the precipitate will dissolve just below the boiling-point and will separate out again on cooling. No precipitate is produced on neutralization with alkali or on the addition of dilute or concentrated acetic acid, or by passing carbonic acid through the diluted urine. This last reaction distinguishes it from globulin and can be made use of to separate these substances.

Hydrochloric acid acts like nitric acid, but the urine, on boiling with an excess of the acid, assumes a violet color. It gives proteid reactions with Millon's reagent and also with copper sulphate and alkali (biuret). Strong precipitates are produced by tannic acid, picric acid, potassium ferrocyanide and acetic acid; also by acetic acid and concentrated salt solution. It is completely precipitable by alcohol and can thus be removed from the urine. The white, flocculent precipitate produced by the alcohol is soluble in water and coagulates at 52° to 60° C. Instead of precipitation by alcohol, it may be isolated from the urine, according to Salkowski, by strongly acidulating the urine with the acetic acid and then saturating it with common salt. The precipitate, after washing, can be purified by dialysis.

A very peculiar characteristic of hemi-albumose is that it may exist in the urine in *deposit* as well as in solution. When in solution it coagulates at about 50° C. (122° F.), and, on further heating, as already stated, the precipitate redissolves and then, on sub-

sequent cooling, reappears. Kühne has named the variety which exists in solution as genuine hemi-albumose and the insoluble variety as coagulated hemi-albumose. Now, this insoluble or coagulated hemi-albumose occurs in digestive fluids, and may also occur in urine as an amorphous granular deposit. The nature of this amorphous deposit can be ascertained in the following manner.

It is first extracted with water, then with dilute acetic acid or alkali. The coagulated hemi-albumose is easily soluble in very dilute acids and alkalies, and the solution on neutralization can be precipitated by alcohol. The precipitate thus obtained is first washed with alcohol and then dissolved in water. On the addition of a little common salt and warming, it should coagulate at between 40° to 60° C. (104° to 140° F.), and clear up again at near the boiling point.

In the presence of serum albumin and globulin, it can be detected by saturating the urine, strongly acidulated with acetic acid, with sodium chloride, boiling and filtering whilst hot. The albumin and globulin remain behind on the filter, whilst the hemi-albumose passes through and separates out as the filtrate cools.

By the term peptone we understand those end-products of the digestion of proteid substances which differ from the albumins proper in their solubility, diffusibility and in not coagulating either by heat or acids. So far as we know, the peptones do not possess the same composition, but differ among themselves according to the source, the particular proteid from which they are derived. The rarity of peptone which occurs in the urine is commonly regarded as deriving its origin from pus corpuscles, which, as we know, may be present in a large number of pathological instances. According to Hofmeister,[1] these corpuscles experience a rapid decomposition, yielding, as one of the products, peptone.

Peptone may occur in the urine in the presence of serum-albumin, globulin or hemi-albumose, though it is not necessarily so accompanied. Indeed, the accompaniment of albumin and its congeners by peptone is rather an exception than a rule; a fact which is all the more striking, since we now know that the normal urine contains peptic as well as tryptic ferments. We would expect on *a priori* grounds, that when albumin, or any other proteid, is present in the urine, it would be acted upon by the ferments normally present and yield peptones. Further investigation is necessary in order to bring out more clearly not only the exact origin of the peptones in the urine, but also the significance they bear, if any, with regard to disease. It should be stated, however, that peptones may occur in the urine of healthy persons, though in very minute quantity.

When peptone is present in the urine in relevant quantity, it constitutes the so-called peptonuria, about which, however, very little is known. Peptones are characterized by their ready solubility in water, great diffusibility and in not giving precipitates with heat or acids. They are furthermore distinguished from albumin, globulin and hemi-albumose in not giving a precipitate with acetic acid and potassium ferrocyanide. They are, however, precipitated by metaphosphoric acid, phosphomolybdic acid, phosphotungstic acid, as well as by tannic and picric acids. The precipitate of the latter redissolves on heating, thus differing from that of albumin. According to Hofmeister,[1] the amount of peptone ordinarily present in the urine is so slight as to be insufficient to yield a precipitate with picric acid.

Peptones may be readily detected in the urine, if the other proteid substances are present or not. In the absence of other proteids the best plan is to add neutral acetate of lead as long as a precipitate forms, then to filter. To the filtrate, which should give no precipitate with acetic acid and potassium ferrocyanide (absence of albumin, etc.), about one-fifth of its volume of concentrated acetic acid is added, and then phosphotungstic acid, acidulated with acetic acid, when, if any peptone be present, a milky precipitate will appear.

In the presence of other proteids, the urine cannot be tested directly for peptone, but these constituents must first be removed. For this purpose the method of Hofmeister[2] is the best one we have and is carried out in the following manner: To about a pint of the urine two and a half drachms of concentrated sodium acetate solution are added, then a concentrated solution of ferric chloride till a blood-red color is developed. The acid solution is now neutralized with alkali as nearly as possible, boiled for a few minutes and, when cold, filtered. If care is taken to have the solution neutral or but slightly acid, all of the albumin, etc., will be precipitated, whilst the peptone will remain in solution and can be detected in the filtrate. This should give no precipitate with acetic acid and potassium ferrocyanide, but if peptone is present it will give a precipitate when it is acidified with acetic acid and an acetic solution of sodium phosphotungstate is added. This is the most delicate reagent for peptone and gives, according to Wolfenden, a distinct reaction in 1 to 100,000.

TESTS FOR ALBUMIN.

The oldest and best known tests for albumin are heat and nitric acid; but, of late years, a large

[1] Zeitschr. f. Physiol. Chemie, 4, 253.

[1] Zeitschr. f. Anal. Chem., 23, 116.

[2] Journal of Physiology, 7, 237.

number of new reagents have been proposed, some of which are of rather doubtful value. It was, therefore, desirable to compare as many as possible of these new tests, not only with reference to their behavior to normal urine, but also with respect to their delicacy in detecting variable amounts of albumin. For this purpose eighteen specimens of normal urine and five albuminous urines, some containing only traces of albumin, were examined with the following reagents, and the results obtained are sufficient to show the utter unreliableness of a large number of these so-called improved tests. It seems to me that the medical profession cannot exercise too much caution in accepting a new test or reagent which is intended to supply the place of the old but reliable ones. Every now and then we see some one come forward with an alkaloidal reagent and launch it forth as a delicate and characteristic test for albumin. These reagents, though they may be exceedingly delicate when pure solutions of albumin are examined, yet, when applied directly to the urine, not infrequently indicate albumin even when it is entirely absent.

1. *Heat and nitric acid.*—Only seven samples of urine gave, on warming, precipitates (of phosphates) which readily dissolved upon the addition of either acetic or nitric acid. That is, to say heat and acetic or nitric acid gave no precipitate in eighteen urines. Nitric acid is to be preferred to acetic acid, inasmuch as the test is much more delicate. If the urine is neutral or alkaline, it should be acidulated with a drop or two of acetic acid. The test is best applied by placing about eighty minims of urine into a test-tube and raising the upper portion to the boiling temperature. Whether a precipitate forms or not, about one-tenth volume (five to ten drops) of nitric acid is added; if a permanent cloud or precipitate remains, albumin is present.

2. *Nitric acid alone. Heller's contact test.*—To about a drachm of urine in a test-tube about half a drachm of concentrated nitric acid is added in such a way that the liquids do not intermix, but form two distinct layers. A grayish precipitate of albumin will soon form at the plane of contact; but when the albumin is present in minute quantity, it is necessary to wait a few minutes. A white, amorphous precipitate of urates may come down when the urine is concentrated, but it is distinguished from that of albumin by forming, not at the plane of contact, but higher up in the liquid and, moreover, by its ready solubility upon the application of heat. The test is very conclusive and extremely delicate. It is said to be capable of indicating as little as 0.003 per cent. of albumin. It was not given by any of the eighteen specimens of normal urine, but failed in the case of one very slightly albuminous urine. This method of testing for albumin is nearly, though not quite, as delicate as No. 1.

3. *Nitric acid and magnesium sulphate* (Roberts's reagent)[1].—This is prepared by adding one volume of seventy per cent. nitric acid (specific gravity 1.42) to five volumes of a saturated solution of magnesium sulphate. The solution is placed in a test-tube and an equal bulk of urine cautiously added, so as to form a layer. If albumin is present, an opalescence will appear at the zone of contact. This test is in every respect inferior to No. 2 and, moreover, gave clouds in six out of the eighteen normal urines.

4. *Acetic acid and sulphate of soda* (Hoppe-Seyler[2]). This test is applied by adding, to about eighty minims of urine previously acidulated with acetic acid, an equal volume of a saturated solution of sodium sulphate and raising the mixture to boiling. A white precipitate or cloud indicates albumin. This test is given preference by Struve,[2] but in this examination it was found to give a very slight reaction with one normal urine, whilst, on the other hand, one slightly albuminous urine failed to respond. In respect to delicacy it is equal to No. 3.

5. *Hydrochloric acid and salt* (Roberts's brine test)[3].—This reagent is a saturated solution of common salt containing one per cent. of hydrochloric acid. It was first proposed by Roberts, but has since been abandoned by him because of its liability to give precipitates in non-albuminous urines. It was found to give reactions with three normal urines. In delicacy it was inferior to any of the preceding and about equal to the heat and acetic acid test.

6. *Picric acid test.*—This was first employed by Galipe,[4] and more recently has been strongly recommended by Johnson,[5] Saul[6] and others. To the filtered urine, free from mucus, under examination an equal volume of a saturated aqueous solution of picric acid is added, when if albumin is present a heavy precipitate will form. As Jaffe[7] has pointed out, picric acid will induce in normal urine, especially on standing, a precipitate consisting of uric acid and of the picrate of the double salt of potassium and creatinin. These, however, are both readily soluble on warming, whereas the albumin precipitate is insoluble. Hence in applying the test any precipitate that appears should be heated. Hemialbumose and peptone yield precipitates with picric acid which are distinguished from that of serum-albumin by dissolving upon the application of heat. It produced a slight cloudiness in three out of

[6] Pharm. Journ. and Trans., 17, 855.
[7] Zeitschr. f. physiol. Chemie, 10.

eighteen specimens under examination and in delicacy was found to equal No. 2, the nitric acid contact test.

7. *Picric acid* (Hager's modification[1]).—This is applied by adding five drops of pure hydrochloric acid to two and a half drachms of the urine, and then a layer of about one-half its volume of a cold saturated picric acid solution. If even a trace of albumin is present, a cloud will appear at the place of contact. In sixteen specimens it was found to yield precipitates which consisted chiefly of the characteristic groups of needles of creatinin picrate. This modification cannot be said to possess any advantage over picric acid alone.

8. *Acetic acid and potassium ferrocyanide* (Bödeker's reaction).—This test is regarded by Hilger[2] as one of the most delicate, if not most conclusive, of albumin tests, and in this examination it showed a reliableness thoroughly in accordance with its previous reputation. It certainly deserves a prominent position along with the heat and nitric acid test and is equally delicate. It gave only a very slight cloudiness in one instance. To apply the test the urine is acidulated with acetic acid, and then a few drops of potassium ferrocyanide added. Hemialbumose likewise yields a precipitate, but peptones do not.

9. *Trichloracetic acid.*—Raabe[3] has highly recommended the use of this compound as a reagent for albumin in urine. A crystal of the acid is added to about sixteen minims of the clear filtered urine, and as it dissolves it yields a clouded zone if albumin is present. Normal urine is said to give a similar reaction in the presence of urates. Nine specimens of urine out of the eighteen under examination gave distinct clouds. In delicacy it is equal to No. 4.

10. *Haslam's ferric chloride test.*[4]—The urine is acidulated with acetic acid, a few drops of sodium chloride added and then a layer of ferric chloride. If albumin is present a white cloud is said to form at the zone of contact. Precipitates were obtained by this test with all of the urines. It is not a delicate reagent even for pure albumin solutions.

11. *Méhu's reagent.*[5]—This consists of one part phenol, one part acetic acid and two parts water or alcohol. It has been examined by Simon,[6] and is considered by him as the most delicate and trustworthy reagent for albumin. In my examination it proved itself to be as reliable as Haslam's test, inasmuch as it also gave precipitates with the entire eighteen urines. In delicacy it is equal to Roberts's brine test.

12. *Mercuric chloride.*—A five per cent. solution was employed, and when applied to pure solutions of albumin it was very delicate, probably more so than the heat and nitric acid test: but in testing urine it is worthless, inasmuch as it gave precipitates with the entire eighteen samples.

13. *Potassium mercuric iodide.*—The use of this alkaloidal reagent as a test for albumin has been recommended by Tanret,[1] not only for qualitative but also for quantitative purposes. It produced cloudiness in sixteen out of eighteen urines under examination. Otherwise it is as delicate as No. 12.

14. *Potassium xanthate.*[2]—This gave precipitates with only four urines, but is not a delicate reagent.

15. *Tannic acid.*—Like the solution of mercuric chloride, it is inapplicable in testing for albumin in the urine. It gave precipitates with the entire eighteen specimens.

16. *Sodium tungstate.*—This is also one of the most sensitive reagents for albumin when in pure solution, but is worthless when examining urine. It gave clouds in seventeen cases.

From what has been said in regard to these different tests, it will be seen that the number of those which are really applicable for testing for albumin in the urine is very small and, indeed, can be restricted to only four. These in respect to their delicacy and applicability can be arranged in the following order.

1. Warming with subsequent use of nitric acid, not acetic acid. This test, if properly used, will give as distinct reaction for minute traces as the most delicate alkaloidal reagent.

2. *The nitric acid and contact method.* This test is almost as delicate as the preceding and is free from any source of error.

3. Acetic acid and potassium ferrocyanide. This is a very sensitive reagent, and does not produce, in normal urine, any precipitate, or at most, in isolated cases, a slight cloudiness.

4. *Picric acid.* This reagent cannot be said to be as delicate as either of the three preceding, and, moreover, the number of normal urines with which it gives reactions is quite considerable.

CASE OF A MINIE-BALL EXTRACTED FROM THE PELVIS TWENTY-THREE YEARS AFTER THE WOUND.

Healing of the Fistulous Fecal Track Afterward by Injections of Dilute Carbolic Acid and Iodine.

BY T. L. OGIER, M.D.,
OF CHARLESTON, S. C.

Je le pansai et Dieu le guerit was the axiom of the celebrated Ambrose Paré on the recovery of some of his most serious and hopeless cases of surgery. And where is the experienced surgeon who has not

[1] Centralbl. f. d. med. Wissensch., 1877, 493.
[2] Zeitschr. f. Anal. Chem., 21, 579.

felt the force of this truth: how often have we seen it in cases of abortion or premature delivery, when the placenta or parts of the fœtus were retained in spite of all our efforts to extract them until the decomposition of the fetor was so great as to make us dread septicæmia and fatal results; yet to find our patient recover without our sad apprehensions being realized, and the reverse in another, and under similar circumstances, when extraction has been easily and thoroughly done, and all antiseptic precautions have been strictly observed to find our patient feverish, the skin pale, temperature high, finally delirium and death from blood poisoning.

This sometimes occurs in other cases notwithstanding the great improvements of antiseptic surgery which now enable us to perform, successfully, operations which before were considered impossible. The great advantage of this system in all cases of surgery and gynecology is so evident that nearly all surgeons now give their patients the benefit of it, but yet patients will die when we do not expect them to, and get well when it seems as if they must die.

The following case verifying the axiom, "*Je le pansai et Dieu le guerit*," I think worth reporting for the following reasons: first, that the patient did not die from the immediate effect of his wound; second, that the ball with bone imbedded in it should have remained in the body for twenty-two years with a sac or cellular tissue forming around it; but, instead, travelling in several directions, coming to a place where it could be diagnosed and extracted successfully, and, finally, the complete obliteration of the fistulous tract by compound iodine injections; healing of the external wound, and the restoration of the patient to health.

CASE.—In one of the last battles of the late war, just before the surrender (at Appomattox Bridge), Capt. L. I. W. received a wound on the left side, three inches below the middle of the crest of the ileum, the ball crushing through the bone at this point was lost in the pelvis. Urine is said to have flowed through the external wound and bloody urine was passed, naturally, for some days after.

Capt. W. remained in hospital about six weeks, during which time his improvement continued; finally, the external wound healed, and his urine became clear, and he left for his home in Charleston.

After he arrived here he suffered little from the wound and attended to his business as rice and cotton factor, but a year later he complained of some trouble in his bowels, the feces came apparently to a certain point in the bowel, but would come no further. I prescribed warm salt and water injections which relieved him; some months after this he complained of the same trouble, and upon introducing my finger into the rectum, high up, I discovered a hard lump on the back and left side of the rectum and pressing on it. By the use of the warm salt and water injections, night and morning, this disappeared, and there was no further trouble for about three years; when, upon pressing with his hand on the lower part of the buttock, he felt and heard a gurgling sound as though there was air in a fluid in the part. Upon examination I found that such was the case, there was no swelling or enlargement of the part, but upon pressing on the buttock just below and within the tuberosity of the ischium a distinct gurgling could be felt and heard: how to account for it I could not, but that there was a sac containing the ball or some foreign substance I had no doubt: how the gas or air got into it I could not see, for if it came from the bowel fecal matter would enter the sac, a fecal abscess would be formed and open either into the rectum or point externally. Nothing of this kind occurred, the patient felt no pain or inconvenience and went about and attended to his ordinary duties, the bowels were regular and the appetite good, still the gurgling could be made evident by pressure.

In about six weeks this ceased to trouble him and it disappeared, and I saw him no more until May 8th, last, when he sent for me in consequence of feeling a hard lump when he pressed hard on the inner side of the tuberosity of the ischium.

On examination just about one and a half inches external to the right end of the usual incision in the perineum, made when operating for calculus, a hard lump could be felt. It was evidently the ball or a piece of bone knocked off by it, so placing the patient over the back of a chair with his hands resting on the seat of it, an incision about three and a half inches long was made in the skin, deepened gradually until the knife touched the foreign substance. This was then laid bare so as to admit of its being seized and I introduced the forceps and extracted it.

It proved to be a minie-ball split from the point nearly to its base by a piece of bone which it grasped firmly.

There was very little hemorrhage, and about two or three ounces of a bloody fluid escaped; the depth of the wound from the skin to the ball was three inches, in length three and a half inches.

After all oozing had ceased the wound was washed with a solution of chloride of zinc, a small tent introduced into the inferior end of the incision to act as a drainage, the lips drawn together and kept in place by rubber plaster, a layer of carbolated cotton was laid over this and secured by a bandage around the pelvis; fluid continued to flow from the lower end of the wound along the drainage-tent, the patient feeling no inconvenience.

On the fourth day the dressings were removed, the lips of the wound united down to the situation of the tent. A seidlitz powder was now given as the

bowels had not been moved since the operation; this acted freely and comfortably and everything went on satisfactorily and naturally, the patient having an operation from the bowels every twenty-four hours, until the ninth day, when our patient had a chill, became feverish and lost his appetite. Three grains of quinine were given three times a day; chicken-broth and beef-tea only for nourishment.

No second chill followed, and on the eleventh day pulse became natural, but on the twelfth day distinct fecal matter was mixed with the fluid discharged from the wound, and upon giving an enema, the water of the injection came through the wound as well as through the anus when the patient made an effort of defecation. The rectum was now well washed out with warm water and explored by the finger with a probe in the external wound without success, but upon pushing the finger very high up near the upper part of the sacrum, a slight depression could be felt, and by bending a long probe and introducing it from the wound, it entered through this depression into the rectum, and felt there by the finger, thus showing a complete fistula.

The opening in the gut was six inches from the anus and ten inches from the wound made for the extraction of the ball.

With the internal orifice of the fistula so high up in the rectum, and the external opening four inches from the anus and ten inches from rectal opening it was a serious consideration as to the proper means to be used for its care. To have operated by laying the rectum open from the internal to the external opening I do not think would have succeeded, and certainly could not be thought of in the present condition of the patient's health; for, since his chill of the ninth day, after the operation his appetite never fully returned, and he lost flesh and was pale and feeble, so we determined to build up his strength by quinine, tonics and nourishing foods; keep him in bed entirely, wash out the wound and keep it clean, inject the canal with a solution of iodine and carbolic acid, and insert a tent dipped in a solution of iodine and carbolic acid, double the strength of the injection up the opening in the rectum, this tent to remain in until the following day; if it was expelled, another was to be inserted immediately after cleansing the canal.

The treatment was kept up for several weeks, the canal becoming narrower, and only slight traces of fecal matter in the discharges from the wound. The iodine solution was now made a little stronger and used for a week, but not thrown up with much force; by the fourth week no fecal matter was perceived, and the fluid discharge from the fistulous track was so slight that the compound iodine injections were stopped entirely and the tent introduced for only one-half inch, for three more days, then the lips of the wound allowed to heal entirely; the patient feeling perfectly well and having operations from his bowels without any inconvenience.

In the seventh week from the time of the extraction of the ball he left the city for the mountains, where he regained all his lost strength and returned in five weeks more a well man.

Many cases of fistula in ano have been treated by injections, but as far as I know of, had to be operated on for their final cure.

The operation of laying the fistulous track open from the upper to the lower orifice, keeping the surfaces from contact until the space fills up, is considered the cure for fistula in ano. In this case the direct cause of postponing any operation was the patient's feeble condition, not wishing to cause additional irritation to his system, and even with his system in good condition it is very doubtful if the wound in the rectum so high up would have closed or the extensive fistulous track ever have healed. That my patient should, under the above treatment, have recovered was most gratifying and unexpected. "*Je le pansai Dieu le guerit.*"

In a similar case I should try the same treatment and hope for the same result.

MEDICAL PROGRESS.

The Treatment of Chronic Constipation.—According to the experience of Bueler, of Berne (*Corr. Bl. für Schweiz. Ärzte*, 1888), the most effective remedy in the treatment of chronic constipation is massage of the abdominal walls. This does not imply a mechanical, indiscriminate following of the movements directed by various authors, but the massage is to be differently conducted with regard to the varying causes of the constipation and the individuality of the case. If the trouble is essentially due to deficiency of the abdominal tension, with relative integrity of the muscular layer of the intestine, deep, powerful massage is indicated at the beginning, to arouse reflex contractions of the recti abdominis. If, however, there is atony of the intestinal muscular layer, as in the case of those of sedentary occupation and little muscular exercise, the muscles of the abdominal wall should be irritated as little as possible, but made tolerant of the massage by gentle stroking of the surface with the flattened hand. It is only later that the abdominal walls of such patients may be energetically manipulated. If dyspepsia be the cause of the constipation, massage of the epigastric region will be of good service in propelling the food onward. In several cases of the kind, in which the ingesta ordinarily remained in the stomach for more than two hours, by methodical massage of the epigastric region the food was forced into the duodenum within five or ten minutes, as demonstrated partly by washing out the stomach and partly by the salol test of the urine. In constipation in consequence of neurasthenia, irritation of the skin and ice-bags to the abdominal walls are indicated. Also in constipation resulting from chronic peritonitis and perityphlitis has massage been effective. In all, the author has thus treated twenty cases of chronic constipation, eighteen with permanent success. In one case a relapse occurred.

One case resisted treatment and was discharged as incurable. As a rule, a cure was effected within four to six weeks in eighteen to twenty-five sittings. In explanation of the efficacy of the method, the following are to be considered: 1. The mechanical effect, the stimulating secretion of the intestinal glands, and propelling onward the intestinal contents. 2. The reflex effect, particularly in nervous individuals, at times the muscular layer being more or less intact. 3. The rise in the temperature of the blood of the organs manipulated, at times reaching 1.8° to 5.4° F. 4. Perhaps a chemical action, induced by the accumulation of CO_2 in the veins of the intestinal tract in consequence of the venous hyperæmia of the peritoneum caused by the manipulation. At the same time the peristalsis is increased.—*München. Monatsh.*, August, 1888.

Treatment of Aneurisms.—M. Germain-Sée highly extols the simultaneous use of iodide of potassium and antipyrine. He finds that the latter drug effectually quiets the tumultuous cardiac action, favors the formation of the clot and dissipates, to a remarkable degree, the dyspnœa and terrible pains.

Dujardin-Beaumetz, while recognizing the high value of antipyrine, finds that its continuous use brings out an eruption, and for that reason he prefers phenacetine, which is never toxic and as efficient as antipyrine. —*L'Abeille Médicale*, August 20, 1888.

Treatment of Ununited Fractures.—In the *Reforma Medica* of August 14th a case is related, in which Professor Loreta successfully treated an ununited intracapsular fracture of the neck of the femur, by scraping the fractured surfaces and inserting a bundle of metallic sutures between them. On January 23d, a robust man, aged thirty-six, was admitted into the Bologna clinic with the history of a fall on the left hip nineteen months previously, since which he had been quite unable to stand, and had suffered from constant severe pain, shooting from the left hip-joint into the gluteal region, the point of greatest intensity being over the course of the sciatic nerve. The limb was much wasted, but it was normal in position, and scarcely at all shortened. Flexion and extension of the thigh on the pelvis were almost impossible, but the patient could occasionally execute very slight movements of rotation and abduction. In rotation, he was sometimes conscious of faint crepitus in the trochanteric region. On February 15th, Prof. Loreta operated with full antiseptic precautions. He made a long incision behind the great trochanter, so as to expose the capsule of the joint, when he noticed a depression between the intracapsular and extracapsular portions of the neck of the femur. On moving the limb, it was found that there was a fracture without displacement in that situation. The capsule was then opened, the fibrous tissue between the fragments divided, and the fractured ends carefully freshened by scraping with a raspatory. As it would have been very difficult to wire the fragments, a bundle of from eight to twelve metallic sutures was introduced between them, and brought out at the lower angle of the external wound. The wound was carefully cleansed, a drainage tube inserted, the edges brought together with deep and superficial interrupted sutures and the whole covered with a sublimate dressing. A long outside splint was then applied. Five days after the operation, the bundle of metallic sutures was removed, and the wound healed by first intention. In less than a month the pain had permanently ceased, and fifty-five days after the operation the patient left the hospital, being able, not only to stand, but to walk with no further support than an attendant's hand.—*British Medical Journal*, August 25, 1888.

Creolin as a Mouth Wash and Gargle.—Schnitzler recommends (*Internat. klin. Rundschau*, No. 27) creolin in obstinate forms of angina follicularis, to be brushed or powdered. The taste is unpleasant.

R.—Creolin . . . 1 or 2 parts.—M.
Aquæ destil. vel.
aquæ menth. pip. . 100 to 500 parts.
S.—As gargle.

R.—Creolin . . . 1 to 5 parts.
Aquæ dest. . . . 50 to 100 parts.—M.
S.—Apply with a brush.

R.—Creolin . . . 1 to 5 parts.
Acid. boric. . . 10 parts.
Ol. menth. pip. . . q. s.
—*Deutsch. medicin. Wochenschr.*, August 16.

Septic Onychia.—This disease, which never gets well by itself and resists even heroic surgical treatment, can be entirely cured, according to Frottier, by antiseptic treatment. He washes the sore with a twenty per cent. solution of phenic acid and covers with iodoform. If the nail is acting as a foreign body, it is carefully removed before the application of the dressing, which is removed every four days, and a fresh one substituted. About three months is required for the perfect reproduction of the nail.—*L'Abeille Médicale*, August 13, 1888.

Salicylic Acid in Metrorrhagia.—Dr. Felici has found salicylic acid arrest the flow in two cases of metrorrhagia in a wonderfully short time, and thinks it should be tried extensively by other medical men in similar cases. His first case was one of carcinoma in which the hemorrhage had been constant and profuse, and had defied all ordinary styptic remedies; a plug of carbolized cotton wool, soaked in a solution of salicylic acid, was applied to the uterus, and completely arrested the hemorrhage within a few minutes. The second case was one of simple metrorrhagia during the menopause, but of so violent a character that the patient became collapsed. Ordinary remedies were tried, with merely temporary effect. Finally, Dr. Felici introduced into the uterus a dossil of cotton wool soaked in a concentrated solution of salicylic acid on the end of the uterine sound. This arrested the hemorrhage in a few seconds and no return occurred.—*Lancet*, August 18, 1888.

The Treatment of Syphilis by Injections of the Yellow Oxide of Mercury in Comparison with Calomel Oil.—Kühn, of Cottbus, states (*Deutsch. medizin. Wochenschr.*, August 2,) that it is generally conceded that injections of calomel are highly useful in the treatment of syphilis. The formation of abscesses is entirely obviated by suspension of the remedy in oil. To determine the relative value of this method of treatment, for almost a year he has largely used injections of the yellow oxide of mercury. Four hundred and twenty-five injections were made in seventy

persons. There were almost exclusively present the affections of the skin and mucous membranes of secondary syphilis. The eruption was always waited for. Topical treatment was avoided. The author has found the results good, but the action not so efficient as after calomel. It appears that four to six injections of calomel have the same effect as six to ten of the yellow oxide. While six, in individual instances, twelve, injections of calomel suffice, twelve to twenty of the yellow oxide are necessary. The following suspensions were used: 1. Calomel vapor parat. gr. xv, olei oliv. optim., ℥ss; 2. Hydrar. oxidg. flav, gr. xv, olei oliv. optim., ℥j. Though it must be conceded that injections of calomel oil are less efficient than those of calomel, on the other hand the reaction following the former are slighter. Abscesses do not form; nor is there notable induration. Stomatitis, which occurred in six cases, was readily checked, so that withdrawal of the treatment was unnecessary. It is believed that with care, barring any special susceptibility to mercury, stomatitis can be entirely avoided. Induration was infrequent. When it occurred, it developed on the day succeeding the injection, disappearing in three to five days. At the time of injecting there was a little pain as in the case of calomel. Comparing the 425 injections of yellow oxide with 272 of calomel as regards reaction, the result is in favor of the former. A number of patients were given injections of yellow oxide and calomel in succession, without recognizing any difference in the fluids used. They volunteered the information, however, that the pain following the calomel injection was the more intense; the induration was more extended, persisting from eight to twelve days, while in the case of the yellow oxide it disappeared in three to five days. The author, in his experiments, used the simplest means, as made necessary during the office hours of a busy practitioner. The strictest antisepsis was observed and the injections were made deeply into the muscles. The patients could not obtain rest of a few hours after the injections, as, on account of the nature of the disease, they desired to avoid conspicuity and any interruption in the pursuit of their avocations. The injections of both preparations were made under precisely similar conditions, so that the comparison ought to furnish accurate results. In conclusion, the author adds that injections of yellow oxide of mercury are certainly very effective, though inferior to inunctions and calomel injections. They commend themselves for their convenience of application, causing locally or constitutionally no complications. They are, therefore, especially adapted to the treatment of walking cases, and are to be preferred as being more convenient, cheaper, more easily managed and less likely to attract attention to the patients. The author usually begins the treatment with the yellow oxide and, if the symptoms speedily disappear, so continues it. The oxide seems specially adapted for slight relapses, in the after-treatment and prophylaxis, viz., to prevent fresh eruptions. Calomel oil was used when the symptoms yielded too slowly to the initial treatment with the yellow oxide and in severe relapses. It is recommended that calomel injections be not entirely excluded from the early treatment, because with fewer injections the less frequent visits of the patient constitute no slight advantage. The injections are suited to the strong and insusceptible. On the other hand, mild relapses in those who bear the injections well might be treated with calomel.

The Antiseptic Influence of Iodoform, the Ethereal Oils and other Substances. The Compression of Gaseous Antiseptics into Gelatin.—As the result of a series of experiments, Ridelix (*Archiv. f. Hygiene*, Bd. 7, S. 309) arrives at the following conclusions:

1. Iodoform acts either as an almost indifferent powder or as a weak antiseptic against the various rod-shaped bacteria. Against cholera vibriones, however, it is a powerful antiseptic, its vapor inhibiting their growth, in ten per cent. solutions of gelatin to the depth of one-fifth to two-fifths of an inch.

2. Oil of turpentine, in one per cent. emulsion, actively inhibits bacterial vegetation. Gelatin cultures, to which is added turpentine 1 : 200, are not adapted to the development of rod-shaped bacteria. On the other hand, a one per cent. emulsion of turpentine does not suffice to destroy the spores of splenic fever. Turpentine itself is actively antiseptic, in a ten per cent gelatin solution finding its way to a depth of three-fifths of an inch, preventing any development in this area.

3. Among the other oils which are antiseptic are those of lavender, eucalyptus and rosemary, but they do not make up into active emulsion. They are themselves distinctly antiseptic. The first two invade a ten per cent. gelatin solution to a depth of two-fifths of an inch, the last to a depth of three-fifths of an inch, and inhibit vegetation to these extents respectively.

4. Of the remaining ethereal oils, oil of olives possesses the strongest antiseptic power. All others, as the oils of thyme, fennel, peppermint, anise and juniper, and camphor are of minor importance as antiseptics.

5. Iodol has proven to be an inefficient, indifferent powder against bacteria.

6. Balsam of Peru is a pretty active antiseptic, acting with peculiar energy upon the cholera vibrio. Placed upon a ten per cent. solution of gelatin, it invades to the depth of three-tenths of an inch and inhibits vegetation.

7. Sodium sulpho-ichthyolate in a five per cent. watery solution has but a weak antiseptic influence.

8. Anilin and saturated anilin water possess conspicuous antiseptic properties. A ten per cent solution of gelatin, to which one-fifth of anilin water has been added is unfit to support bacteria.

9. The experiments upon the compression of gaseous antiseptics into gelatin have shown that gelatin is no inert substance, but that peculiar and extensive diffusive processes take place in it.—*Centralbl. f. die ges. Therap.*, August, 1888.

Nitroglycerin in Migraine and Cephalalgia.—Troussiévitch (*Bulletin Médical*, No. 35) has had favorable results from the use of nitroglycerin in sea-sickness, and particularly in that form of migraine dependent upon contraction of the vessels, especially in those cases in which the pains occur in paroxysms, are increased by compression of the carotids, are diminished by recumbency, and in which, during the seizure, the face is pale. Nitroglycerin is contraindicated in cephalalgia, the result of passive cerebral hyperæmia. The best mode of administration is by dropping a one per cent. solution upon the tongue. Beginning with one drop, to test the susceptibility of the patient, a drop may be added every third day, as necessity demands.—*Deutsch. medicin. Wochenschr.*, July 26, 1888.

Incision of Swollen Optic Nerve Sheath.—MR. BRUDENELL CARTER, at the recent Glasgow meeting of the British Medical Association, gave an account of a method which he had devised of opening the sheath of the optic nerve behind the eye, for the relief of pressure within this sheath and within the cavity of the skull.

The brain is invested by firm membranes, which secrete a certain amount of fluid, and are continued down to the eye in the form of a sheath, which surrounds the optic nerve; and, whenever the pressure within the cavity of the skull is increased, as by the growth of a brain tumor, or even by excess of secretion from the membranes themselves, a superabundance of fluid is apt to find its way down the nerve sheath to the level of the eye, to subject the optic nerve to injurious pressure, and, in many cases, to destroy the sight. It not infrequently happens that the pressure within the brain cavity may be increased by temporary or curable causes, which, nevertheless, continue in action sufficiently long to produce permanent blindness, even although the patient may, in other respects, recover.

In view of these conditions, it was suggested by Dr. de Wecker, of Paris, sixteen or seventeen years ago, that it might be possible to open the optic nerve sheath, and thus not only to relieve the nerve from pressure, and to preserve it from injury, but also, on account of the position of the eye relatively to the brain cavity, to drain the latter by gravitation, and to relieve the brain as well as the eye. Dr. de Wecker made two endeavors to accomplish this object, but he tried to feel his way to the optic nerve without the aid of sight, and to incise the sheath by means of an instrument carrying a concealed knife, capable of being projected by means of a spring. The risks of failure, and, still more, the risks of inflicting irreparable injury upon the nerve, were such that he only attempted his operation in two well-nigh hopeless cases, and only one attempt to follow his example has been recorded.

Mr. Carter's attention was called to the matter last year by a case in which the diminution of pressure within the optic nerve sheath was manifestly desirable; and he devised a method of operating by which the sheath could be exposed to view, and the object attained with certainty, under the guidance of sight at every step of the process. He read before the Medical Society of London, last year, an account of the first case in which he operated, which was successful. The external rectus was divided, the eyeball then rotated inward, the sheath of the optic nerve was exposed and opened, and gave exit to the contained fluid. He read an account of three more cases at Glasgow, in one of which the result was negative, as far as sight was concerned; while in the other two the patients were not only quickly restored to useful vision, in one instance from complete, in the other from nearly complete blindness, but were at the same time relieved or cured of other symptoms, such as headache and sickness arising from direct pressure on the brain.

In his paper at Glasgow, Mr. Carter claimed for the new operation that it could be performed with certainty and without risk either to life or to any important structure, and that it afforded a reasonable prospect of the preservation of sight in many forms of disease in which it is now habitually or frequently lost. As in the case of every new operation, time and further experience of its effects are required in order to determine the precise limits of its usefulness. In the discussion which followed the paper, Mr. Bickerton, of Liverpool, said that, in consequence of reading the account of Mr. Carter's first case, he had himself performed the operation in two instances, in one of which temporary restoration of sight was followed by relapse, while in the second the ultimate issue was favorable.

Wound of Left Ventricle.—KIANKOFF relates the case of a Cossack who was wounded in his left side at the fourth intercostal space, the blade entering the heart. The wound was cleansed and dressed with a compress. The patient regained consciousness the next day and lived for four weeks. He finally died from attempting to lift a heavy load. The autopsy disclosed a wound in the left ventricle. The pericardium was full of dark bloody matter.—*L'Union Médicale*, August 4, 1888.

New Vesicant.—DR. BONI, in *Union Pharmac.*, recommends the following:

Camphor	2 parts.
Chloral	30 "
Cantharides	10 "

The camphor and chloral are first mixed in a mortar and then warmed. The tincture of cantharides is added last and then thoroughly shaken for fifteen minutes. This preparation is less volatile than the cantharidal collodion, and is especially useful in cases of women and children.—*Journal de Médecine de Paris*, Aug. 12, 1888.

Angina Pectoris.—HECHORD highly recommends the subcutaneous injection of nitro-glycerin; he uses forty drops of a one per cent. solution in alcohol in half an ounce of water, and regulates the dose in accordance with the requirements.

This method, while not curative, greatly ameliorates the suffering and diminishes the frequency of attacks, if perseveringly followed.—*Revue de Thérapeutique.*

A Case of Sudden Blindness.—NOTHNAGEL (*Wiener med. Blätter*, No. 20, 1888) relates the case of a man, forty-six years of age, who, always in good health, barring occasional headache, suddenly became blind, with fully retained consciousness. The somewhat demented patient showed entirely healthy internal organs; the ophthalmoscopic examination was negative, the pupils of varying size, the right somewhat slower to react than the left. A test of the visual field disclosed hemiablepsia superior, though the inferior range of the field was not unimpaired, for only the colors red and white were distinguished and there was no appreciation of the size of objects. The author believes that there was a lesion of the visual field in the cerebral cortex in the occipital lobe. He had already observed simultaneous disease of both occipital lobes, confirmed at the autopsy. The reflex irritability of the pupils excluded a lesion of the optic thalamus or of the corpora quadrigemina.—*Medicin. Chirurg. Rundschau*, August 1, 1888.

Methylal as an Hypnotic.—M. BOURBILA has been experimenting with this drug and, in certain nervous affections, prefers it to chloral, urethan or opiates.

In epilepsy and mental disturbance due to organic lesions, it has proved of value.

Its solubility, harmlessness and pleasant taste and odor unite in making it a superior hypnotic.—*Gazette Hebdomadaire des Sci. Méd.*, August 18, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 15, 1888.

THE SURGICAL TREATMENT OF INTUSSUSCEPTION.

THE discussion upon the treatment of intestinal obstruction at the coming meeting in Washington of the Congress of American Physicians and Surgeons, will doubtless prove to be the auspicious event of the year, in the line of abdominal surgery. And we may certainly expect that it will put many of the at present mooted questions of diagnosis and surgical interference at rest or at least upon a much more substantial and practical basis.

MR. ARTHUR E. J. BARKER has recently successfully and brilliantly operated upon a case of intussusception of the cæcum, ascending and transverse colon, which he reports in the *Lancet* of August 11th, together with some very interesting statistics of operative interference in such cases. His case was of unusual interest. A child, four years old, who had always had the very best of health, came under Mr. Barker's care, with indubitable symptoms of intussusception. He had copious bloody stools, accompanied with great straining and tenesmus, severe abdominal pain and peritonitis decubitus. A well-marked tumor could be made out in the left iliac fossa, but could not be defined by rectal examination. An ineffectual effort to reduce the invagination having failed, abdominal section was proceeded with seventeen hours after the onset of the symptoms. As soon as the median incision had been made, a hand was carried into the abdomen and the tumor, not without considerable difficulty, was reduced by adopting a method of reduction recommended from a theoretical standpoint, some years ago, by Hutchinson. This consists in pushing the tumor upward from below and at the same time retracting the ensheathing bowel with one hand, while with the other gentle traction is made upon that portion of the intestine which enters its upper portion. In this case the reduction was mainly accomplished without bringing the mass into view. The involved bowel was œdematous and in places ecchymotic, but otherwise in good condition. The operation was completed in thirty-five minutes; no drainage was used, and the patient made a rapid and uninterrupted recovery.

Barker's statistics embrace preantiseptic as well as thoroughly antiseptically treated cases, and, consequently, whilst they present a somewhat grim appearance as regards success when contrasted with those of other departments of abdominal surgery, still, when we take into account all of the heretofore usual concomitants of this most desperate class of cases, we must be rather more surprised at the recovery record than at the mortality rate. He has been able to collect 63 cases of intussusception of all varieties which were treated by abdominal section—in most of them probably undertaken as a very last resort. Of this total, 38 were children, with a mortality of 87 per cent., and 25 were adults, with a death-rate of 68 per cent.

In all, 13 recovered and 50 died—a mortality of 74 per cent. Section was performed in 34 cases and the bowel released (including Barker's own case), with a mortality of 65 per cent. In 29 cases the intussusception was found irreducible. Of these 29 operations 5 must be classed as exploratory, as no treatment of the invagination was attempted; in 14 the affected bowel was resected, and in the remaining 10 artificial ani were formed. But a single one of these 29 cases recovered—that of an adult whose intussusception was resected.

We think that these figures alone more than justify the author's modest conclusion that a larger array would probably strengthen his belief that abdominal section "compares favorably with other methods of treating this very fatal condition."

Indeed, such a method of treatment should be practically always successful if we could make our diagnosis and operate during an early stage of the disease, before the patient had lost almost all chances which might have been in his favor, through exhaustion and septic absorption.

A METHOD OF WIRING FRACTURES OF THE PATELLA.

THE treatment of transverse fractures of the patella is confessedly unsatisfactory, and the ideal method which will yield a perfect result and expose the patient to no danger has yet to be discovered. Very many different methods of treatment and various forms of apparatus have been devised for the reparation of this injury. Most surgeons are content to use splints in uncomplicated acute cases and are measurably satisfied with their results. A few use Malgaigne's hooks, hoping thereby to gain a closer union of the fragments, and claim good functional results. Others who worship at the shrine of Listerism, boldly advocate and practise incision into the joint, removal of interposed fibrous tissue, clots, and effusion and the immediate approximation of the fragments with wire. By all of these methods good functional results have been obtained, and under all have there been many failures. When splints alone are used union occurs through the interposition of fibrous tissue, which if not more than half an inch in length is probably as useful as if the continuity of the bone had been entirely restored. Even when the separation is much greater, there is usually but slight disability; and the crowning virtue of the treatment is its perfect safety.

On the other hand, the advocates of incision and wiring do usually obtain bony union, good functional results and a marked shortening of the time of treatment; but it cannot be said that the method is free from danger, either to life or limb. In some cases inflammation, suppuration and necrosis supervene, in some amputation of the thigh becomes necessary, in a percentage, by no means small, death has resulted; and in some which have safely passed these stages, there are stiffness and partial ankylosis of the joint. In view of these casualities many surgeons who are thoroughly imbued with the principles of aseptic surgery, and versed in its technique, have rejected the open incision and immediate suture, and make use of apparatus of various kinds.

As a contribution toward the solution of the best method of treating fractures of the patella, DR. W. L. AXFORD, of Chicago, has devised "A method of wiring fractures of the patella," which is published in the *Annals of Surgery* for July.

In order to limit effusion and abort inflammation, the limb immediately upon the occurrence of fracture should be placed on a posterior splint, and soft sheeps'-wool sponges applied over and to the side of the joint and snugly held in place by a roller bandage. Ice water should be kept constantly trickling upon the sponges for forty-eight hours, at the end of which time the knee will probably be ready for the operation. If the effusion is still too great, it may be removed by Schede's method, and if the fragments cannot be brought together, the ligamentum patellæ may be detached from the tibia. The fibrous aponeuroses should be removed by rubbing the surfaces together or by passing a tenotome between the fragments and separating the interposed tissues. For the purpose of wiring the fragments, a long Brainard's drill is used, the point of which is perforated to allow the wire to be passed. Two drills are necessary. The fragments being held together, one drill is entered from above and passed through the fragments in a direction parallel to the long axis of the limb. The drill is detached from the handle and left temporarily *in situ;* the other drill is passed in the opposite direction from the first, the wire threaded into the eye at its point, and the drill withdrawn bringing the wire with it. The first drill is threaded in the same way and withdrawn, and the wires are twisted. A few layers of gauze are placed over the knee, the twisted ends of the wires pushed through the gauze, and a cap of hard rubber, leather or felt perforated is applied over all. The wires are now twisted tightly and a Bavarian or plastic splint applied.

Dr. Axford thinks this method presents a minimum danger of infection when stringent antisepsis is enforced, and that there is a good chance to obtain bony union. This method, in part of its execution, is very like that advocated by Dr. T. G. Morton, of Philadelphia, a few years ago, and we do not see that it presents any particular advantages over Morton's procedure. Dr. Morton passed his pins as in the above method, and, placing shoulders over their extremities, allowed them to remain. They would certainly approximate the fragments as well as the wires. We think either method preferable to the open section. No operation of this nature should be performed except with the observance of all necessary antiseptic precautions.

THE POISONOUS EFFECTS OF CIGARETTE-SMOKING.

THE experimental investigation by Dr. Dudley of the cause of the poisonous effects of cigarette-smoking, presented on another page of THE MEDICAL NEWS, has led him to ascribe it mainly to carbonic

oxide produced by the process of combustion. The difference in the effects of smoking a cigarette and a pipe or cigar he holds to be due entirely to a difference in the methods of smoking. By the inhalation of the smoke the carbonic oxide is brought in position for absorption in the lungs and acts injuriously upon the blood by deoxidizing it. Were the smoke of a cigar or pipe inhaled in the same manner as that in cigarette-smoking it would be just as injurious. The experiments made upon mice, which were placed in a confined atmosphere thoroughly impregnated with cigarette-smoke, showed that the carbonic oxide quickly destroyed life, proving it to be a most noxious constituent of tobacco-smoke.

Dr. Dudley rejects the explanation that the poisonous action of cigarette-smoking is due to the adulteration of the tobacco with drugs, such as opium, or to arsenic contained in the paper. Nicotianine is poisonous, but it is not peculiar to the cigarette. The deleterious effects of the cigarette-habit are, therefore, not due to anything peculiar in the composition of the cigarette, but to the practice of inhaling the smoke. It follows, therefore, that tobacco-smoking is injurious in proportion as the smoke is inhaled. That the most poisonous constituent of tobacco-smoke is carbonic oxide seems indicated by Dr. Dudley's investigation, but further experimentation may demonstrate a different conclusion.

The first triennial Congress of American Physicians and Surgeons assembles in Washington next week, and the indications point to a most successful meeting.

The initial number of a new weekly medical journal, to be called *The Illustrated Medical News*, is announced to be published in London on September 29th. Its distinctive features will be an original colored plate with each number, and numerous woodcuts in illustration of the text.

The Canadian Medical Association met in annual convention, at Ottawa, during the past week. Among those who were on the programme to present papers were Drs. Howard, Fenwick, Roddick, Alloway, Shepherd, Stirling, Mills, Blackader, Laphthorn Smith, James Bell, Canniff and Playter; also, Dr. Osler, of this city, whose subject was the "Mortality of Pneumonia." The *Montreal Medical Journal* laments greatly that the French-Canadian fraternity has hitherto held aloof from this representative medical body of the Dominion, and earnestly urges that element to put its shoulder to the medical wheel at the Ottawa meeting, to the advantage of every element.

REVIEWS.

Laryngology and Rhinoscopy in the Diagnosis and Treatment of Diseases of the Throat and Nose. By Prosser James, M.D. Fifth edition enlarged; illustrated with hand-colored plates. 12mo. pp. 273. London: Ballière, Tindall & Cox, 1888.

To the older laryngoscopist Dr. Prosser James is well known as a pioneer in modern laryngology. The present edition of his manual, much of which has been rewritten, condensed and rearranged, is a marked improvement on the former ones in material, in diction and in illustration. We note a claim for devising the nasal dilator known as Fränkel's, the use of which has done much to stimulate researches in rhinoscopy and to develop knowledge of diseases of the interior of the nose. The subject of intubation of the larynx is given due prominence, and the apparatus of O'Dwyer is well illustrated. Cutting sickle-shaped knives devised by the author are presented as admirably adapted for the excision of certain morbid growths of the larynx, and for excision of the uvula and the tonsils. The Jarvis snare is duly recommended for the purposes for which it was contrived; but for some of them the author has found it more advantageous to use a bent canula instead of the straight one. We notice an illustration of an exceedingly delicate pair of nasal forceps for the removal of foreign bodies. As far as our recollection serves, these are the main, fresh features of this new edition of a valuable little treatise for practitioners entering upon the special study of diseases of the throat and of the nasal passages.

CORRESPONDENCE.

THE SUCCESSFUL PALLIATION OF HAY FEVER.

To the Editor of The Medical News,

Sir: It may interest some of your readers to hear the details of a palliative treatment of hay fever which has secured almost entire relief to a patient who had submitted to a thorough, yet unsuccessful, course of radical treatment with the galvano-cautery, caustic acids, chisels, saws, etc.

The drugs employed, atropine and cocaine, are well known in connection with this disease, but the mode of their use may be novel. The patient is directed to take $\frac{1}{200}$th grain of atropine sulphate on rising, and to repeat the dose every four hours till bedtime. If any dose fails to check running from the nose, it may be repeated in half an hour. Should dryness of the nose continue longer than four hours, the atropine may be withheld until renewal of the flow. Incipient dryness of the mouth is a safe and convenient indication to use in limiting the dosage of the drug. The effects of atropine are two: First, it diminishes exalted peripheral sensibility, and thus renders the nose less sensitive to the

special irritant cause of hay fever; sneezing is diminished or abolished, and with it a train of distressing symptoms. Secondly, it checks the watery secretion of the nose, and thus prevents washing away of the cocaine before it has practically reached the surface to which it must be applied.

For the local use of cocaine the wire cotton-carrier, shown in the cut, is the most convenient instrument yet

Cotton-carrier. ¾ full size.

devised. It is made of spring-tempered German silver, or brass wire one-twenty-fourth inch thick, with a ring formed at one end, the body curved at right angles to the plane of the ring, and the tip *longitudinally* scratched with a fine file or sand-paper in order to engage the cotton when rotated in it. The total length of the finished instrument is six inches. The wire must, of course, be annealed *near the sharp bends*, by heating red-hot and *suddenly quenching*. Iron or steel wire should never be used on account of its liability to rust and break in the nose. A very small quantity of absorbent cotton is twisted about the tip, care being taken to cover the rounded point, and the patient, holding the convex curve uppermost, passes the little finger into the ring and thereby securely grasps an instrument with which he can convey cocaine to all parts of the nose. The physician should perform the first application, touching the turbinated bones and meati on all their surfaces, paying especial attention to the floor of the nose and the anterior commissure. The space thus reached measures approximately four inches horizontally by two inches vertically in its greatest diameters.

During this operation the patient should be directed to notice the variations in sensation, some spots seeming to burn, itch, smart or cause sneezing or lachrymation. These spots should be mentally mapped out by the patient, who thus becomes possessed of a chart of the areas causing his distress. The physician then proceeds similarly with the other nostril and bids the patient to take hold of the instrument while *in situ*, manipulate it for himself, and to withdraw it from its greatest penetration, about four inches. This revelation of his own anatomy inspires confidence, and the physician's assurance that there are no structures in the nose which the patient's sensations will allow him to injure will soon lead to a most surprising ease of self-treatment, with an accuracy of touch and certainty of result impossible for an outsider to attain. With the assistance of atropine internally, weak solutions of cocaine will clear the nose, and therefore relieve other dependent symptoms, such as congestion and itching of the eyes, itching of the roof of the mouth, of the throat, ears and chest, and asthma.

The eyes will rarely need special attention, but in such rare cases they may be gently touched in both corners with a one or two per cent. solution of cocaine on the cotton-carrier, a fresh pledget of cotton being used. For the nose the solution may vary from one-half to four per cent., according to the severity of the case and the time of day, stronger solutions being required on rising and toward evening. It will rarely be necessary to employ a solution stronger than four per cent., a failure of which shows either a failure to reach the peccant area or that the cocaine is being washed away, and therefore indicates another application of cocaine or another dose of atropia.

Compared to this mode of application of cocaine other modes are clumsy, inefficient and wasteful. Atomization and instillation cannot reach the surfaces abnormally jammed together by the engorged bloodvessels, and without this indispensable condition cocaine is worse than useless, because more or less of it will be absorbed by the system, with injurious tendency. This delicate cotton-carrier can separate any surfaces forced together by engorgement, and be allowed to remain in contact with the sensitive spot, while the hands are free for any duty. The camel's-hair brush, which is sometimes used, has a clumsy quill preventing its soft and scattering hairs from reaching the tortuous passages, and it is furthermore dirty and difficult to clean, leading to a rapid deterioration of the cocaine solution. On the contrary, the cotton is readily pushed off the wire with a handkerchief or another piece of cotton, and the wire thus cleansed instantly. The quantity of cocaine used with the wire is very small, two or three grains per day being ample for a severe case. The quantity of atropine, likewise, seems absurdly small, a steady consumption of five granules daily for a month aggregating only three-quarters of a grain. It is very important that the granules of atropine be accurately made. This cannot be done on a small scale and it is therefore best to buy them of a large manufacturing house of good reputation. Wyeth's triturates have been found satisfactory.

The above treatment may be much assisted by general measures. Draughts or exposure to ordinary causes of cold in the head should be avoided, likewise sudden, great changes of light. Dust and respiratory irritants of all kinds are injurious. Sneezing can always be controlled by biting the upper lip, if other means fail, the pain of the bite being increased by a determined effort of will to the point necessary to obliterate the incitement to sneeze. Useless coughing must be strictly repressed. Rapid walking or running upstairs powerfully assist the action of cocaine for obvious reasons, and likewise mental occupation, reading, for instance, often rapidly comforting eyes apparently too photophobic for use. Diet should be ample in quantity, and non-inflammatory in quality. The hours of sleep should be prolonged.

These measures are the result of a large number of experiments, and as they have secured practical immunity to a severe case of twenty years' standing, they are recommended in confidence as a means readily available for every practitioner to use in relieving this opprobrium of his profession. Their applicability is believed to be general, no reason appearing why a patient should not be nearly as comfortable during his period of hay fever as at other times. Polypi or abnormal growths in the nose should, of course, be removed in any event. With his tiny armamentarium in his pocket the whilom victim has for

three summers fearlessly trampled the rag-weed and breathed through his nose its poisonous pollen, sure of immediate relief from any paroxysm. A. H. L.

NEWS ITEMS.

The University of Michigan.—*The Physician and Surgeon* for September criticises the Board of Regents of this institution for failing to fill the existing vacancy in the chair of Obstetrics and Gynecology and Diseases of Women and Children. The medical faculty had selected and recommended a candidate eminently fitted and qualified for the position; a man who is known and recognized by the medical profession through his writings and his success in the practice of his branch, as one of the leading gynecologists of this country. But the Board was shown one objection to making the appointment which more than counterbalanced all these intrinsic qualifications. Through the reputation of his ability, he has built up a large and lucrative practice in the city of Detroit; and not being willing to sacrifice this and reside in Ann Arbor, the appointment was not made, because it has been decided that in the future all appointees to professorships in the *medical* department must live in Ann Arbor.

It seems as if the regents have an actual fear that by employing men having the reputation of clinical workers and clinical teachers, it might appear that they regarded clinical instruction an essential feature in medical education. To admit this would not be consistent with their persistent neglect to provide facilities for such instruction; their indifference to the requests of those who are faithfully laboring to build up a clinic; and their opposition to the movement that will furnish the medical department with the greatest amount of clinical advantages.

Epidemic Disease.—An important memorandum on the proceedings which are advisable in places attacked or threatened with epidemic disease, which has been drawn up by Dr. George Buchanan, F.R.S., has been issued to sanitary authorities by the Local Government Board. In this memorandum it is stated that, wherever there is prevalence or threatening of cholera, diphtheria, fever or any other epidemic disease, it is of more than common importance that the statutory powers conferred upon sanitary authorities for the protection of the public health should be well exercised by those authorities acting with the advice of their medical officers of health.

Proper precautions are equally requisite for all classes of society. But it is chiefly with regard to the poorer population, therefore, chiefly in the courts and alleys of towns, and at the laborers' cottages of country districts, that local authorities are called upon to exercise vigilance and to proffer information and advice. Common lodging-houses and houses which are sublet to several small holdings always require particular attention.

Wherever there is accumulation, stink or soakage of house refuge or of other decaying animal or vegetable matter, the nuisance should as promptly as possible be abated, and precaution should be taken not to let it recur. Especially examination should be made as to the efficient working of sewers and drains, and any defect therein, and any nuisance therefrom, or from any foul ditches or ponds, should be got rid of without delay. The ventilation of sewers, the ventilation and trapping of house drains and the disconnection of cistern overflows and sink pipes from drains, should be carefully seen to. The scavenging of the district and the state of receptacles for excrement and of dust-bins will require close attention. In slaughter-houses, and wherever animals are kept, strict cleanliness should be enforced.

In the removal of filth during periods of epidemic disease it is commonly necessary to employ chemical agents for reducing or removing the offence and harm which may be involved in the disturbance of the filth. In the removal of privy contents these agents are more particularly wanted if the disease in question be cholera or enteric fever. The chemical agent should be used liberally over all exposed surfaces from which filth has been removed. Unpaved earth close to dwellings, if it be sodden with slops or filth, ought to be treated in the same way.

Sources of water supply should be well examined. Water from sources which can be in any way tainted by animal or vegetable refuse, especially those into which there may be any leakage or filtration from sewers, drains, cesspools or foul ditches, ought no longer to be drunk. Above all, where the disease is cholera, diarrhœa or enteric fever, it is essential that no impure water be drunk.

The liability of leaky pipes to act as land drains and to receive foul matters as well as land drainage through their leaks is not to be overlooked. And such leaky pipes, running full of water with considerable velocity, are liable to receive, by lateral insuction at their points of leakage, external matters that may be dangerous. This latter fact is not recognized so generally as it should be, and ignorance of it has probably baffled many inquiries in cases where water services have in truth been the means of spreading disease.

If, unfortunately, the only water which for a time can be got should be open to suspicion of dangerous organic impurity, it ought at least to be boiled before it is used for drinking, but then not to be drunk later than twenty-four hours after it has been boiled. Filtering of the ordinary kind cannot by itself be trusted to purify water. It cannot be too distinctly understood that dangerous qualities of water are not obviated by the addition of wine or spirits. When there appears any probable relation between the distribution of disease and of milk supplies, the cleanliness of dairies, the purity of the water used in them, the health of the persons employed about them, and the health of the cows that furnish milk should always be carefully investigated. Even apart from any apprehension of milk being concerned in a particular outbreak of disease, it is desirable that English people should adopt the custom, which is always followed in some Continental countries, of boiling all milk at once upon its reception into a house.

The washing and lime-whiting of unclean premises, especially of such as are densely occupied, should be pressed with all practicable despatch.

Overcrowding should be prevented, especially where disease has begun, the sick room should, as far as possible, be free from persons who are of no use to the patient,

Ample ventilation should be enforced. It should be seen that windows are made to open, and that they are

sufficiently opened. Especially where any kind of infective fever has begun. It is essential, both for patients and for persons who are about them, that the sick room and the sick house be constantly traversed by streams of fresh air.

The cleanliest domestic habits should be enjoined. Refuse matters should be speedily removed or destroyed; and things which have to be disinfected or cleansed should always be disinfected or cleansed without delay.

Special precautions of cleanliness and disinfection are necessary with regard to infective matters discharged from the bodies of the sick. Among discharges which it is proper to treat as infective are those which come in cases of smallpox and scarlatina from the affected skin; in cases of cholera and enteric fever from the intestinal canal; in cases of diphtheria and scarlatina from the nose and throat; likewise, in cases of any eruptive or other epidemic fever, the general exhalations of the sick. The caution which is necessary with regard to such matters must, of course, extend to whatever is imbued with them; so that bedding, clothing, towels, handkerchiefs and other articles which have been in use by the sick may not become sources of mischief, either in the house to which they belong or in houses to which they are conveyed. So far as articles of this class can be replaced by rags, or things of small value, it is best to use such things and burn them when they are soiled. Otherwise clothing and infected articles should be subjected to the disinfection of the sick room, or be removed for disinfection by heat.

In enteric fever and cholera the evacuation should be regarded as capable of communicating an infectious quality to any night-soil with which they are mingled in privies, drains or cesspools; and after such disinfection of the mass is practicable, they should be disposed of without delay and under the safest conditions that local circumstances permit. They should not be thrown unto any fixed privy receptacle, and above all, they must never be cast where they can run or soak into sources of drinking water.

All reasonable care should be taken not to allow infective disease to spread by the unnecessary association of sick with healthy persons. This care is requisite, not only with regard to the sick house, but likewise with regard to schools and other establishments wherein members of many different households are accustomed to meet.

If disease begins in houses where the sick person cannot be properly accommodated and tended, medical advice should be taken as to the propriety of removing him to an infirmary or hospital. Every sanitary authority should have in readiness a hospital for the reception of such cases.

Where dangerous conditions of residence cannot be promptly remedied, it will be best that the inmates, while unattacked by disease, remove to some safer lodging.

Privation, as predisposing to disease, may require special measures of relief.

In certain cases special medical arrangements are necessary. For instance, as cases of cholera in this country often begin somewhat gradually in the comparatively tractable form of what is called "premonitory diarrhœa," it is essential that, where cholera has appeared, arrangements should be made for affording medical relief without delay to persons attacked, even slightly, with looseness of bowels. So, again, where smallpox is the prevailing disease, it is essential that all unvaccinated persons (unless they previously have had smallpox) should very promptly be vaccinated; and that revaccination should be performed in cases properly requiring it.

It is always to be desired that the people should, as far as possible, know what real precautions they can take against the disease which threatens them, what vigilance is needed with regard to its early symptoms, and what (if any) special arrangements have been made for giving medical assistance within the district. For the purpose of such information printed hand-bills or placards may usefully be employed, and in cases where danger is great house-to-house visitation by discreet and competent persons may be of the utmost service, both in quieting unreasonable alarm and in leading or assisting the less educated and the destitute parts of the population to do what is needful for safety.

The present memorandum relates to occasions of emergency. Therefore the measures suggested in it are essentially of an extemporaneous kind; and permanent provisions for securing the public health have, in express terms, been but little insisted on. It is to be remembered, however, that in proportion as a district is habitually well cared for by the sanitary authority, the more formidable emergencies of epidemic disease are not likely to arise in it.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 4 TO SEPTEMBER 10, 1888.

A Board of Medical Officers, to consist of CHARLES H. ALDEN, *Major and Surgeon;* GEORGE M. STERNBERG, *Major and Surgeon;* HENRY MCELDERRY, *Major and Surgeon;* and EDWARD C. CARTER, *Captain and Assistant Surgeon,* is constituted to meet in New York City, on October 1, 1888, or as soon thereafter as possible, for the examination of Assistant Surgeons for promotion, and of candidates for admission to the Medical Corps of the Army.—*S. O. 203, A. G. O.*, September 1, 1888.

WORTHINGTON, J. C., *Captain and Assistant Surgeon.*—Ordered from Fort Crawford, Colorado, to Fort Townsend, Washington Territory.—*S. O. 206, A. G. O.*, September 5, 1888.

HALL, J. D., *Captain and Assistant Surgeon.*—Ordered from Fort Townsend, Washington Territory, to Fort Niagara, N. Y.—*S. O. 206, A. G. O.*, September 5, 1888.

BROWN, P. R., *Captain and Assistant Surgeon.*—Ordered from Fort Niagara, N. Y., to Fort Sidney, Nebraska.—*S. O. 206, A. G. O.*, September 5, 1888.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING SEPTEMBER 10, 1888.

PURVIANCE, GEORGE, *Surgeon.*—To proceed to Fairport, Ohio, as Inspector, August 27, 1888.

MURRAY, R. D., *Surgeon.*—To proceed to Key West, Fla., September 5, 1888.

HUTTON, W. H. H., *Surgeon.*—To take temporary command of Camp Perry, Fla., September 8, 1888.

GUITÉRAS, JOHN, *Passed Assistant Surgeon.*—To proceed to Jacksonville, Fla.; after return from duty, on special train from Jacksonville, to Hendersonville, N. C., September 8, 1888.

BRATTON, W. D., *Passed Assistant Surgeon.*—To proceed to San Francisco, Cal., and report to Surgeon H. W. Sawtelle, for duty, September 8, 1888.

WASDIN, EUGENE, *Passed Assistant Surgeon.*—To rejoin his station at Mobile, Ala., September 5, 1888.

MAGRUDER, G. M., *Assistant Surgeon.*—To proceed to Mobile, Ala., and assume temporary charge of the Service, Aug. 31, 1888.

FATIIC, J. B., *Assistant Surgeon.*—To proceed to Memphis, Tenn., and relieve Passed Assistant Surgeon C. T. Peckham, August 31, 1888.

MAGRUDER, G. M., *Assistant Surgeon.*—To proceed to Way Cross, Ga., September 6, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LIII. SATURDAY, SEPTEMBER 22, 1888. NO. 12.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS, WASHINGTON, 1888.

THE PRESIDENT'S ADDRESS.

Delivered September 20, 1888.

ON MEDICAL MUSEUMS,

With special reference to the Army Medical Museum at Washington.

BY JOHN S. BILLINGS, M.D.,
SURGEON, U. S. A.

GENTLEMEN OF THE CONGRESS: Our articles of confederation require that the President shall give an address. In endeavoring to comply with this regulation I must ask your indulgence, for, while I think I have something to say, I cannot give you such a discourse as would befit the audience, the occasion and the subject.

The prominent characteristic of the great majority of the societies composing this Congress is that their members have, as a rule, been chosen because they have either made some valuable contribution to medical literature, or have, in some way, rendered aid to the profession; in other words, they are supposed to be men whose labor and thought have not been confined to their own interests, or to those of their own patients. It may, therefore, be assumed that you are all interested in medical science, not merely as a means of giving new modes of diagnosis or of treatment, but also for its own sake, for the sake of knowing, for the pleasure of investigation, and in the hope of helping others, and that, while the majority have devoted themselves more or less to special branches, they have not, in so doing, lost interest in what may be for the general good of the whole profession.

I am here as the representative of the medical departments of the general government, which has need of the best knowledge of all the specialties, and is beginning, in its turn, to do something for each.

The physicians in the government service are all general practitioners, and are expected to have such an education and training as will fit them to deal, alone and without consultation, with the diseases and injuries to which men, women, and children are liable. You have been, and still are, their teachers—in the lecture-room and the hospital before they entered the service—in your text-books, monographs, and contributions to journals or transactions which follow them to their widely scattered posts of duty. They are your warm friends; the more you discover, the greater your skill, the more recognition which your work receives, the better they are pleased.

Within the last twenty-five years the general government has, in its turn, done something for medicine and for you, by founding and maintaining a medical library and museum in Washington under the direction of the Medical Department of the Army.

I have had occasion several times to call attention to the library, which no doubt is that part most immediately useful to physicians, and which has attracted most attention. To-night I propose to speak of the other branch, in whose proper development it is desirable that you should take an intelligent interest, and after giving a brief sketch of the development of modern medical museums we will consider more especially our own national medical collection as it is, and as it ought to be.

The origin of collections of objects of natural history was possibly, as suggested by Beekman, the custom of keeping curious objects in temples; but we have no record of the formation of any collections specially connected with anatomy or medicine before the sixteenth century. It is true that human anatomy had been introduced in the schools by Mundinus in 1306, and that no doubt in Bologna, in Paris, and a few other places, a skeleton or two was preserved for purposes of instruction; but alcohol was unknown as a preservative before the end of the fifteenth century, anatomical details were of no interest until Vesalius had stirred up controversy with the Galenists, and injected preparations were not thought of until after Harvey's announcement, in 1628, of the discovery of the circulation of the blood.

The introduction of the use of the microscope at the beginning of the seventeenth century, and the collections of preparations for use with this instrument made by Leeuwenhoek and Ruysch, gave a powerful stimulus to formation of museums of this kind. The most famous of these collections was that of Ruysch, purchased in 1717 by Peter the Great, and sent to St. Petersburg. Ruysch was practically the first to prepare injected anatomical specimens for permanent preservation, and, if the stories told of his work are true, he made preparations which have never been surpassed. His museum was a very ornamental one, the bones and skeletons being arranged in various devices, the plants in bouquets, while scattered through the whole were beautifully engrossed sentences from the Latin poets.

The most famous medical museum in the latter half of the eighteenth century was that founded by Fontana, at Florence. This still exists, filling a series of rooms, and consists mainly of wax preparations, beautiful to look at, but inaccurate, and of little scientific value.[1]

[1] The first use of wax models to represent pathological specimens or dissected preparations of parts of the human body is attributed to a Sicilian priest, Gaetan Jules Zambo, who lived in the latter part of the seventeenth century, and who had been accustomed to make wax models of diseased or deformed hands, feet, etc., to be used as *ex voto* offerings at the shrines of certain saints. The fame of these induced a Florentine surgeon, Ricci, to visit the priest and to get him to model some pathological specimens which he furnished. A Franciscan, named Desrones, brought this art to France, and made many such models between

During the first half of the present century a number of private collections were formed by anatomists, pathologists and surgeons. Most of these have become public collections, either by gift or purchase, and the rest have been dispersed or destroyed. There is not in existence, at the present time, any large collection of specimens pertaining to human pathology which is the property of an individual, and is at all comparable to those made by John or William Hunter, Astley Cooper, Howship, Liston or others. Commenting on this fact, Sir James Paget writes me that he does not know of any large private pathological collection, and that he believes the change to be entirely for the better.

The necessities of modern progress in anatomy, physiology and pathology, have led to the creation of medical museums in all parts of the civilized world. In most of the continental capitals these are connected with universities supported by the state. In Great Britain and in this country they are, as a rule, connected with private, or semi-private institutions for medical teaching. This difference is connected with the relative position which medicine holds in the educational machinery of the state in different countries. Where medical education is furnished by institutions directly supported by the government, the museums, which are a part of the apparatus required, are, of course, also supported by the government.

Through the aid of friends, whose kindness in replying, or in obtaining replies, to somewhat troublesome inquiries, I cannot sufficiently acknowledge, I have obtained certain data with regard to some of the most important medical museums now existing in the world, and a part of these data are summarized in the table before you. Evidently the city having the most valuable aggregate of anatomical and pathological specimens at the present time, is London, which contains the collections of the Royal College of Surgeons, of St. Thomas's, Guy's, St. Bartholomew's, St. George's and other hospitals, and of University College, the College of Physicians and others. The oldest public anatomical museum in London is probably that of St. Bartholomew's, which, in 1726, had a room set apart for the purpose under the charge of John Freke, and which received the private collection of Abernethy. The most important medical museum in the world, and the one which has exercised the greatest influence in giving direction to anatomical and pathological studies, and in serving as a model for the formation of other collections, is undoubtedly that of the Royal College of Surgeons of London, the foundation of which was the collection made by John Hunter, purchased by the government in 1799. In one sense it is not a government institution, the funds from which it is now supported not coming directly from government grants; but, in another sense, it is truly such, since the College may be looked upon as an agent of the government having special charge of matters connected with medical education, as it is the principal examining body for those proposing to practise surgery in Great Britain.

the years 1703–1706, and Bianchi formed a large collection of the same kind in Italy. It was scattered after his death, and the last vestiges of it were two models representing a healthy and a diseased liver, which were to be seen in Innspruck in 1766. (Percy et Laurent, in Dict. des Sci. Méd., Paris, 1818, vol. xxxv., article "Museum.")

The great value of the Hunterian collection lies in the breadth of its scope, which includes every branch of medical science; but it is preëminent in illustrations of human morphology and its abnormities. The museums of the great hospital medical schools are relatively richer in the department of pathological anatomy, specimens of which they have greater facilities for obtaining. Among these there is, of course, a certain amount of duplication of matters of interest; but no two pathological specimens are precisely alike, and the question discussed in the Paris school one hundred and fifty years ago, viz.: "An pro distinctis ægris ægritudines diversæ?" is one that often occurs to a curator as he examines new specimens which differ but little from those already in his collection, but which do differ in some respects, and with regard to which he must decide as to whether, upon the whole, they are worth the trouble and cost of preservation.

Edinburgh and Dublin have also each large and valuable collections pertaining to anatomy and medicine.[1] In Paris the medical museums are those of the Faculty of Medicine, including the Musée Dupuytren devoted to pathological anatomy, and the Musée Orfila devoted to human and comparative anatomy, materia medica, natural history and instruments and apparatus.

Professor Leon Le Fort, to whom I am indebted for data with regard to these collections, remarks that a large proportion of the anatomical specimens of the Orfila museum come from candidates who take part in concours opened for positions connected with the anatomical teaching of the faculty—such as prosectors, demonstrators, etc., each candidate being required to furnish from ten to thirty specimens.

The medical museums of other European countries are connected as a rule with universities, and it is to be remembered that in these the different branches of medical instruction are each both more specialized and more comprehensive than is the rule with us. The professor of anatomy, of physiology, of pathology, has each his own building or institute, and, therefore, each his own museum; and unless this fact be held in view, comparisons between Continental and English, or American, medical collections may give very erroneous results.

With regard to the museums connected with American Medical Schools I will say little, referring you to the table and appended notes for such data as I have been able to collect. I am aware that in so doing I put aside a splendid opportunity to enlarge upon the general superiority of all these collections and the peculiar excellences of each, but I think that you all know as much about these as I do and there is time only for details with regard to the one American Museum in which I am specially interested. I will say only that the best museum connected with a medical school in this country is the Warren Museum in Boston, and that the history of the collections of wax models, upon which several of our museums have expended large sums of money, is very instructive as to how not to do it.

[1] I am indebted to Sir James Paget for the information given with regard to the greater number of the British museums. I had originally intended to attempt to obtain such data only from four or five of the largest; but on sending my little list of questions to Sir James he took such a kindly interest in the matter as to send a copy of these queries to a number of other museums with the request that they might be answered.

So far as mere number of specimens is concerned our own national medical collection is one of the eight largest in the world, and is increasing more rapidly than any other.

This collection, known as the Army Medical Museum, owes its inception to Dr. Wm. A. Hammond, one of whose first acts after becoming Surgeon-General, in 1862, was to issue a circular stating that "as it is proposed to establish in Washington an Army Medical Museum, medical officers are directed diligently to collect and to forward to the office of the Surgeon-General, all specimens of morbid anatomy, surgical or medical, which may be regarded as valuable; together with projectiles and foreign bodies removed, and such other matters as may prove of interest in the study of military medicine or surgery."[1] By the end of the year over a thousand specimens had been collected, and the catalogue printed in 1866 showed that it contained 7716 specimens. It is not my purpose in this address to trace the history of its development; that must be done elsewhere. It has recently been placed, with the Library, in a conveniently arranged fire-proof building, and on the first of July last contained over 15,000 specimens besides those contained in its microscopical department, divided as follows:

Comparative Anatomy	1,689
Pathological	8,354
Medals	384
Microscopical specimens	10,416
Normal Human Anatomy	2,961
Instruments and Apparatus	814
Microscopes	141
Miscellaneous	835

Besides these there are 375 specimens pertaining to normal human anatomy and 726 to pathological anatomy, which are in what is called the provisional series.

It is not, however, by number of specimens that the importance and value of museums of this kind can be judged; and in this case such a comparison would give an exaggerated and erroneous idea of the value of this collection. My object in this address is not to boast of what we have, but to indicate what we want; to point out what a National Medical Museum, arranged to meet the wants and interests of this country, should be, should have, and should do, and to suggest some of the ways in which this is to be brought about.

At first the Army Medical Museum was limited to military medical subjects, but of late years its scope has been greatly broadened, and is now nearly the same as that of the Royal College of Surgeons. It includes human anatomy, physiology, pathology, somatological anthropology, instruments and apparatus, and illustrations of methods of teaching connected with special departments of practical medicine. It does not at present include hygiene or materia medica, except in their immediate relations to the military medical service, and this for reasons which will be stated presently. That our National Medical Museum should be broad and comprehensive in its scope there can be no doubt, its requirements in this respect being quite different from those of collections formed and used more especially for the purpose of teaching medical students. The most practically valuable of these last are those formed by individual professors to suit their own specialties and methods of teaching. They need not, as a rule, be large. I may even say that they should not be large; for the labor of properly preserving a large collection is great, and the student, with his limited time and want of knowledge of what to look for, can examine but few specimens so as to profit by them. For the same reason specimens of rare abnormities, of double monstrosities, etc., are of little use in ordinary medical teaching as given in this country, and are not specially desirable in the museums of our medical schools.

You may have noticed that, in speaking of the scope of our museum, I said it included "human anatomy." This phrase does not mean that it has no specimens illustrating the structure of other animals,—for it has many, and needs many more; but it means that in this department its main purpose is not to make comparative anatomy an end to itself by exhibiting all known variations in structure throughout the animal kingdom as a basis for their study in relation to development and environment, causation and results. In other words, it is not an anatomical museum but a medical museum. The broad field of general biology, including natural history and comparative anatomy, will ultimately be covered by the National Museum, and in our medical collection it will be quite enough to illustrate human anatomy fully, using so much of the structure of the lower animals as will be useful in explaining why certain parts of the human body are thus, and so, and not otherwise. No sharp line of distinction can be drawn between the field of work of the general, and that of the medical museum. So far as morphology is concerned, they must necessarily overlap somewhat, since both want a certain number of the same specimens although using them to illustrate different points of view.

The medical museum should possess a series of specimens showing the normal anatomy of the domestic animals, or of animals used in experimental pathology, pharmacology or physiology as a basis for comparison with abnormal or pathological specimens derived from the same animals. It is in the section of embryology, illustrating laws of heredity and development, that specimens from the lower animals are most interesting, and this is especially the case in the study of human abnormities and monstrosities. It is quite possible that to some anatomists it may seem that no limitation should be placed to the scope of the museum in this direction, for it is easy to trace some connection between any variation in structure in any animal and some structure, normal or abnormal, in man, but the limitation is placed, with reference to the work of the National Museum, so as to secure the best results.[1]

The kind of specimens most valued for illustrating anatomy in a museum is now very different from what was sought for in the first half of this century. Dried and varnished dissections showing bloodvessels, etc., are now looked on as nearly useless, and are kept only as

[1] Circular No. 2, Surgeon-General's Office, Washington, D. C., May 21, 1862.

[1] In the great majority of medical schools in this country anatomical teaching has a much more limited field than in the German universities, and our professors of anatomy, following English traditions, are usually in training for surgery. We have, however, several who are devoting their entire work to anatomy in the broad sense, and for its own sake, and it is in this direction that progress will be made.

historical relics. Elaborate dissections under alcohol, mounted in opaque dishes, with flat glass covers, and sections of frozen bodies, similarly mounted, are what the student and the practitioner most desire to see. In our museum there are some excellent specimens of this kind, prepared under the direction of Professor His, of Leipzig; of Professor Cunningham, of Dublin; and by our own anatomist, Dr. Wortman. These, however, are only samples to show how the work should be done. We require several hundred such specimens to illustrate properly regional anatomy in relation to age and sex, while the possible applications of the same methods to the illustration of visceral displacements, hernias and deformities of all kinds are boundless. As regards physiology, but little can be done by museum specimens to illustrate function as distinguished from form and structure. The so-called physiological series in the Hunterian collection, is a series of organs illustrating variations in different families of the animal kingdom or at different ages; in other words, it illustrates ontogenic and phylogenic development. The things students or teachers of physiology are most anxious to see in a museum are specimens of instruments and apparatus employed in experimental physiology, or in the measurement of the special work of different organs, or in illustrating lectures on physiology. Illustrations of results obtained in experimental pathology often belong quite as much to physiology, as, for example, specimens of results of Gudden's atrophy method.

The Army Medical Museum has a only a beginning of such an anatomical collection as I have indicated as desirable. Like all other museums, it is richer in specimens illustrating osteology than in any other branch of anatomy, simply because such specimens are the easiest to obtain and preserve. We are accustomed to think that human anatomy is nearly exhausted as a field for original research, and that, at all events, every important organ or muscle or nerve has been figured, described and named. Granting this, so far as the adult is concerned, although it is by no means true even for him, we have still to study the development of each of these organs or groups of organs, as seen at different ages, and, for some of them, in different races. As fast as these points are seen to be of practical interest, either in connection with diagnosis or the surgical treatment of disease, they are investigated; but an ideal museum should furnish the investigator the means for his researches; and it must, therefore, collect specimens without special regard to what is at present known to be their practical interest. The collection of such series of specimens of each joint, region and organ, as I have in mind, including sections and dissections at different ages from the earliest appearance in fœtal life to extreme old age in man, and in many cases in the lower animals, is a slow process. Such specimens, and especially such series of specimens, can only be prepared by a skilled anatomist, and there are few such; hence, the formation of our ideal anatomical collection, limited though its scope may be, must be a work of time.[1]

[1] As Sir William Turner remarks: "Where a question in human embryology hinges upon an examination of parts in a very early state of development, we have often to wait for many years before an appropriate specimen falls into the hands of a competent observer."

There is ample material and scope for original work for half a dozen skilled anatomists for many years to come to supply the demands of this museum for illustrations of human morphology in its various relations, and it is not desirable to scatter effort over too wide a field.

The pathological section of a medical museum is its main feature, being, as Mr. Flower remarks, the section to which, in the eyes of Hunter and his successors, all others form merely the introduction. It is true that to some physicians specimens in this department seem to have little value; but they are balanced by those physicians whose chief interest in a case of disease is to get a post-mortem. No doubt much of the ancient pathology, and some of that which is quite recent, is comparable to the looking in the dark for a black spot which is not there, but those who despise pathology, and devote their entire attention to symptoms and treatment, err as much on one side as those who talk and act as if a knowledge of pathological anatomy could take the place of clinical experience do on the other. I do not know, however, that the doctrine usually preached, viz., that each man should attain the just mean in his views, is a true one. Certainly it is not the principle on which the universe seems to be constructed; the balance is maintained, not by having everything exactly symmetrical, but by excess in one direction balancing excess in another.

To secure pathological specimens in their most instructive forms for museum purposes requires, in many cases, not only considerable variation from the usual routine methods of post-mortem examinations, but very considerable delay in ascertaining the results. If, for example, we wish the best specimens of the results of cerebral disease, the brain must not be removed and sliced up in the usual manner; it should be hardened *in situ* to a certain extent, and its sections should be carefully considered with reference to their preservation in their relations to each other before they are actually made. There is need of a treatise by a skilled pathological anatomist giving such methods in detail from the modern point of view.

One of the most important sections of our museum is that devoted to microscopy, including normal and pathological histology and photomicrographic work. In the cabinets there are nearly 11,000 mounted specimens, illustrating almost every field of microscopical research. Many of these were made twenty years ago and more, and were mounted by processes which have not given good results, so that Dr. Gray, who is in charge of this section, estimates that about 3000 will be set aside as worthless; but the rest form a very valuable series to which additions are being constantly made, and materials for which we are specially anxious to obtain. In connection with this section a series of cultures of chromogenic and pathogenic bacteria is kept up for museum exhibits, and also to illustrate methods of work.

While the great majority of the specimens in a medical museum have some relation to diagnosis, prognosis, or therapeutics, the number of those which are of direct interest to the so-called practical physician is not very great. It includes models and casts illustrating dermatology, morbid growths, the results of amputations, excisions, plastic operations, etc., and instruments, apparatus, dressings, etc., of all kinds. Here also may be

classed hospital fittings and furniture, means of transportation for sick and wounded, model cases of instruments, emergency chests, etc. Our medical museum has a fair beginning of a collection of this kind, including over a thousand specimens; but many more are needed to make it reasonably complete. If each medical man who devises a stethoscope, a pessary, a speculum, an ophthalmoscope, or an electro-therapeutic appliance with which he is well pleased, would send a specimen to the collection, its increase would certainly be rapid, and it could always show the latest improvement.

An ideal medical museum should be very complete in the department of preventive medicine, or hygiene. It is a wide field, covering, as it does, air, water, food, clothing, habitations, geology, meteorology, occupations, etc., in their relations to the production or prevention of disease, and thus far has had little place in medical museums, being taken up as a specialty in the half dozen museums of hygiene which now exist.

Our own National Museum of Hygiene is, as you know, under the direction of the Medical Department of the Navy. It is a very interesting collection of sanitary appliances of various kinds; but it is not well housed, is much overcrowded, and its location is so inconvenient that it receives but few visitors, and, therefore, has by no means the educational influence that it ought to have. It should be provided with ample quarters in the immediate vicinity of the National and of the Army Medical Museums, to both of which it would form a very desirable supplement. In our medical museum, at present, military hygiene only is illustrated, and this only in a few branches, such as hospitals, means of transportation of wounded, etc. As regards materia medica, an exceedingly well arranged collection, including about 5,000 specimens, has been formed in the National Museum, under the direction of the Surgeon-General of the United States Navy, by Dr. J. M. Flint, of that service. The relations of materia medica to natural history, commerce, and the arts, which are subjects belonging especially to the National Museum, are as close as they are to medicine, and I am very glad that our national collection in this branch is where it is, and under its present management. In the Medical Museum we have a collection showing what is supplied in the way of drugs, instruments, etc., to the medical department of our army, and, as opportunity offers, we shall extend this to include the medical supplies of other armies or services.

The extent to, and manner in, which a medical museum should deal with anthropological and ethnological problems are not questions to be discussed in the abstract with advantage, since the answers must differ greatly according to circumstances. In our National Museums the matter has been so arranged that all material relating to anthropometry, or to real or supposed structural differences in man according to race, are cared for in the Medical Museum, while specimens illustrating manners and customs, implements, weapons, clothing, pottery, etc., are taken charge of in the anthropological division of the National collection.

The Army Medical Museum contains what may seem a large amount of material relating to human osteology, and especially craniology, in its relations to North American ethnology, or the history of the development of different varieties of man on this continent; but it is not actually half large enough to permit of drawing definite scientific conclusions from it. The majority of the crania which it contains have been measured to a certain extent, and the results have been published; but many other measurements are desirable to permit of comparison with series taken elsewhere, and even measurements already made must be repeated by later and better methods. We have been trying some experiments with composite photography and superimposed contour tracings as a means of obtaining typical outlines and dimensions for race groups of crania, and these give promise of good results. If the collections of crania of North American Indians in Boston, New York, Philadelphia and Washington could be brought together, a very much better average presentation of the majority of tribes or groups would be obtained than can be furnished by either of these collections taken separately. By composite photography and tracings, combined with uniform methods of measurement, we can practically bring these collections together, and obtain results nearly as satisfactory as if we had them all in one room. We have also fitted up one large room with instruments and apparatus for anthropometry in its widest sense, including psychophysical investigation, and it is intended to make this a complete laboratory for illustration of methods of work.

In London arrangements have been made to have such an anthropometric laboratory in an outbuilding at the South Kensington Museum. The two things have no connection, and it seems to have been placed there because it would obtain more visitors desirous of being measured and tested than if placed anywhere else. In this laboratory, which is, I believe, essentially the same sort of institution as that arranged by Mr. Francis Galton at the Health Exhibition in 1884, and is planned by Mr. Galton, any person can have the regular series of measurements and tests made upon himself for a charge of six cents. There are difficulties in the way of making a charge for such measurements in a government establishment, and there are also difficulties in undertaking to do such work gratis, chiefly on account of the cost. It is, however, so desirable that it should be done, and the data which such observations systematically carried on for a series of years would be so valuable, not only from a scientific point of view, but for practical purposes in connection with life insurance interests, and very possibly with practical medicine, that we should endeavor so overcome these difficulties in some way, and I think it can be done sufficiently, at least, to stimulate private enterprise in this direction. It is possible that we may yet see in large cities establishments of this kind, directed by skilled and reputable physicians having the confidence of the profession, where not only normal but abnormal conditions can be determined; places where the secretions can be tested chemically and microscopically, ophthalmoscopic and endoscopic examinations of all kinds made, the mode of functioning of muscles and nerves determined, and an authoritative record of the results made for the use of the individual, as evidence of his condition, or for the information of his physician. It would require an already established reputation and much skill and tact on the part of the director of such a laboratory, with absolute refusal to give prescriptions or advice in any shape, to make it fully successful; but it may be done.

An important feature of our national medical museum

should be to show methods of research and of instruction for the benefit of the investigators and teachers of the country. This includes instruments and apparatus, and, to a limited extent, illustrations of the modes of using them and of the results; it also includes diagrams, models, etc., used for illustrating lectures. For example, as soon as Koch's researches became known in this country, physicians, and especially medical teachers who visited the museum, asked if we could show them the apparatus used by Koch and Pasteur in bacteriological work, and eagerly examined the few specimens of cultures on solid media which we were able to exhibit. The anatomist comes to the museum quite as much to see methods of mounting and preservation, as to see the specimens themselves; the physiologist does not expect to see function directly exhibited, but he does hope to find information about kymographs and constant temperature apparatus, and he wants to see whether Kühne's artificial eye is so useful for teaching purposes that he ought to get one to illustrate his lectures.

In what has been said thus far, it is chiefly the utilitarian point of view that has been made use of; but this is by no means the whole matter. No art, and no branch of science should form the sole end and object of a well balanced life, and there are objects in every large museum which are of great interest, though they appeal rather to the emotional than the intellectual faculties of the spectator. There are many specimens in the Army Medical Museum which I would rather see removed than to lose John Hunter's lancet, which has no scientific interest whatever. So also its collection of between three and four hundred medals and tokens relating to medical institutions or distinguished medical men, or commemorating outbreaks of pestilence or the victories of preventive medicine, is one which should be made complete and fully displayed, though it would not be easy to demonstrate its utility to any one unless he were interested in the history of the struggles and triumphs of the medical profession.

The objects of a medical museum are to preserve, to diffuse and to increase knowledge. Its conservative function is to form a permanent record of what has been demonstrated and to fix the meaning of terms. Even in my brief experience of thirty years the terminology of anatomy, physiology, pathology, chemistry and of most of the specialties has greatly changed, and this not only by addition of new terms, but by the dropping of old ones. To get useful results from the older literature we must know the precise significance of the old words, and, in some cases, the best way to learn this is to examine the specimens prepared by those who used such terms in their descriptions. The specimens in our museum which came from the collections of Professor William Gibson and Dr. Frank Hastings Hamilton are especially valuable, because they were the basis of practical teachings, and should be examined by any one criticising these teachings.

A large proportion of the pathological specimens in this museum illustrate conditions which now rarely occur, forming a group which it is safe to predict will never be duplicated. It is not only that they were gathered during a great war, but that they illustrate the results obtained when antiseptic surgery, as now understood and practised, was unknown. Never again, I hope, will there be brought together such a collection of the effects of pyogenic microörganisms on gunshot wounds, especially of bone, as may be seen in its cases.

The museum also preserves, for future investigations, objects whose nature or relations are not understood at the time when they are received, and which occur so rarely that the means of studying them by comparison can only be obtained through such preservation.

Upon the function of a museum as a diffuser of knowledge;—as a means of education; it is needless to dwell. That it should also strive to increase knowledge is equally certain. This is to be effected by study and comparison of its materials. The results of such study and comparison of a part of the Army Medical Museum collection have appeared in the volumes of the *Medical and Surgical History of the War*. Another part will, I hope, soon be utilized in a study of its collection of human skeletons and crania which has been commenced by Dr. Matthews, of the Army. But a considerable part is as yet only in the stage of agglomeration, and our present business is to collect and preserve, leaving to the future its full utilization.

A medical museum is really used, for purposes of study, by very few persons; but through the teaching of those few its lessons are made known to the whole profession. American physicians in investigating a subject do not, as a rule, think of inquiring as to what museums can show with regard to it, simply because they have not had convenient access to large collections and are not accustomed to make use of them. Thirty years ago we were in much the same situation in respect to medical literature; but as the libraries have grown, desire for bibliographical research has grown also, and I think that in like manner when we have secured a comprehensive National Medical Museum it will not only be made use of, but will give a powerful stimulus to the formation and progress of other more special collections elsewhere.

What should be the relation of this central national collection to those formed in different parts of the country, either in connection with medical schools, or with museums of broader scope? Certainly they should help one another, and this can be done in many ways. I do not in the least object to a generous rivalry to do the best work, to have the most instructive and the most artistic preparations. That is a good thing. But I would say to the anatomist of a school, when you have made a preparation which is noteworthy, offer to make a copy for the national collection, where it will be seen by the anatomists of all schools and of all countries. To the pathologist of a medical school I would say, after you have secured type specimens for your own collection put aside other good specimens for the National Medical Museum, which will furnish you materials for the purpose.

On the other hand, the collections of the National Museum are available for study by any proper person, and its duplicates should be used to aid other museums which may be in special need of them.

In common with several of the largest and most important medical museums, more especially those of the Royal College of Surgeons and of the Faculty of Medicine of Paris, the Army Medical Museum has the advantage of being closely associated with a large medical library which is in the same building, and at present under the same direction. The increased utility and attractiveness which this gives to both library and museum are very decided.

It is true that in some other institutions similarly arranged there has been some grumbling as to the proportion of funds allowed to the museum and to the library respectively, the museum enthusiast claiming that the librarian would rather have one rare old pamphlet than half a dozen entirely new vertebrates, while the bibliophile is sure that the demand of the profession for access to a full supply of books and journals is much greater than that for access to specimens. I can only say, from my own experience, that one who has charge of a library only, will probably not hesitate to take museum funds, if he can get hold of them, to buy books; but that when one person is responsible for both he will endeavor to give each its fair share of the resources at his command.

If we had to choose between having a great national medical library and a great national medical museum, no doubt most of us would take the library, because it would be of more immediate use to us; but no such unpleasant alternative is forced on us. There is no reason why we should not have both, and we must have both.[1]

I have time for only a very condensed statement of the wants of our National Medical Museum. In the first place it needs the intelligent interest and friendship of the medical profession of this country. To a very considerable extent it has had this; were it otherwise it would not be what it is, nor where it is. But it needs more of it, and it can never have too much. Every medical man in this country should help a little and provide for the perpetuation of his name as that of a physician interested in the progress of the profession by sending at least one specimen to it. It is omnivorous in its demands for material, as will be seen by the circular which it has recently issued. But I will name as special wants, human embryos, especially those of a very early age, monstrosities and malformations of all kinds in man or in the lower animals; results of old injuries, such as fractures or dislocations, or of surgical operations, such as excisions, stumps, etc.; injuries and diseases of the eye, ear and nose; new growths of all kinds; diseases of the brain and spinal cord; and specimens illustrating the condition of bones, joints, brain, larynx and other organs in extreme old age.

In the second place it needs a regular supply of funds from the general government. To form and keep in proper condition such a medical museum as this should be is a more difficult and expensive matter than those not acquainted with such work would suppose, and the gifts of specimens from the profession must be supplemented by ample means for the preparation, preservation and proper display of these specimens, and also for the purchase of apparatus and typical specimens of foreign work, in order that the Museum may be always able to show the latest state of knowledge and the best ways of doing things.

The annual appropriation for the Museum at present is $5000. This is sufficient, except that the printing of the catalogue, of which I shall speak presently, must be an extra charge; but the medical profession should see to it that the amount is not reduced in the rhythmic spasms of partial economy with which some of our statesmen are afflicted.

The third need of the Museum is of a series of the right kind of descriptions of its specimens, given on labels and in a catalogue. Unaided by such descriptions it has for each man that which he can see in it, and no more. One man will see nothing but an old piece of bone, a shapeless mass of tissue bleached by alcohol, a case of old, dingy brass instruments. Another will see in the same things a rare joint atrophy, implying curious abnormal nerve influence; a leprous nodule, whose history, if we knew it, would reach back through the lazar-houses of the middle ages to the far east, and whose bacilli may be the lineal descendants of those that vexed Naaman the Syrian; a case of microscopes illustrating the development of that instrument, from the first rough iron tube of the spectacle-maker of Nuremberg to the delicate and complicated instrument through which we now peer curiously into that world which lies within the world of unassisted vision. By our labels and catalogues we must tell men what to see; but to do this we must first see ourselves. The aphorism that a first-class museum would consist of a series of satisfactory labels with specimens attached means a good deal. Something has been done in this direction, as you will see on inspection of the cases; but I often wonder what sort of labels a man who has spent years in investigating the normal and abnormal structure and relations of one organ would write for our specimen of that organ. Such help as this we need; kindly, truthful criticism, the pointing out of errors and of new points of view for this mass of material.

We also need a series of printed catalogues. One of these should be in the form of compact handbooks relating to particular sections of the collection, and intended partly for the use of visitors while in the museum and partly as a ready means of letting distant friends know what material it most needs in different departments. It should also print a complete illustrated catalogue of the whole collection for the use of the investigators and teachers of the profession. Congress has been requested to grant authority for the printing of such a catalogue by the Government Printer. The material for it is nearly ready, and it would make three volumes each the size of one of the volumes of *The Medical and Surgical History of the War of the Rebellion*.

The subject of museum organization and management is one of those with regard to which it has been said that a man who is interested in it passes through three successive states of mind, viz.: First, he thinks he knows almost all about it, except a few minor points of detail which he is going to look up. Second, he feels that he will never know anything about it. Third, he believes he knows a little and hopes by experience and study to know more.

The museum needs earnest and well-trained students to work up its collections so as to advance knowledge, and, at the same time, to display properly the specimens so as to make them most instructive. To all such students we shall endeavor to afford opportunities for this work. Precisely how this is to be effected is not yet clear, but here is abundance to be done, and there are quite a number of men coming on the stage who want to do such work for its own sake, because it gives them

[1] "There are few things in relation to our science of which I am more sure than this, that every possible method of studying it should be by all possible means promoted." Sir James Paget, in Lancet, January 22, 1887, p. 159.

pleasure. Sooner or later we shall have half a dozen or more of specially trained men busy in the laboratories and work-rooms of the museum, each engaged on his own problems, and the whole for the common good.

The medical museum hints at matters which lie outside the scope of known physical and chemical laws. Physicians have not, as a rule, been very virulent theologians; their studies and their daily work tend to give them compensation of bias in this particular, and, therefore, in this age of transition in beliefs, it is not so true of them as of others, that "the old hopes have grown weak, the old fears dim, the old faiths numb." In our medical museum yonder may be found abundant illustrations of the results of physical and chemical actions and reactions upon what was once living matter, and was connected with centres of consciousness, of intellect, of emotions which imply something more than ordinary protoplasm or mere metabolism. It brings together strange company. The men who dwelt on the sides of the Andes in the old Aztec days, the men who built cities in the Gila Valley centuries before the days of Columbus, the Esquimaux, and the Indian of the plains, black and white, red and yellow, all sorts and conditions of men are represented in those bony caskets which once held their centres of life and thought; but now are reckoned only as so many crania in the Museum catalogue. The great majority of the pathological specimens imply either suffering or death, or both, of the individual from whence they came. Some of them are the results of intemperance, of lust, of folly and crime; but some are the results of unselfish sacrifice for the good of others, true flowers of blood and pain. A large group of them form one of the relics of an acute paroxysm of disease of a great nation. The old pensioner likes to keep the battered ball which crippled him, and so these relics have an interest beyond that which is purely professional. That the nation is not crippled by its loss, takes nothing from their interest, and the fact that we are physicians does not imply that we look upon them from a medical or scientific stand only. Those of the combatants who survive are now better friends than ever, and the museum specimens, coming as they do from the sick and wounded of both armies, and contributed by both Union and Confederate surgeons, enforce the lesson of the unity of the profession and of its interests, as well as that of our country.

Our museum, like the library with which it is associated, includes all the specialties. No physician is so learned or skilful that he can find no instruction there, and no one is so ignorant that he cannot comprehend some of the lessons which it teaches. Taken together these institutions should contribute in no small degree to our national prestige, for which eminence in scientific work and teaching is an essential element, and if it be remembered that they are only twenty-five years old, and that during that period we have been making medical history at a tremendous rate, surely some incompleteness and crudeness may well be excused or overlooked.

Speaking in behalf of the army medical department, and for the dead as well as for the living who have been charged with this work, I can truly say that we have been very proud of our charge, and that we have done our best, each according to his capacity and opportunities, to make the museum and library such as a great profession and a great nation have a right to demand.

AMERICAN SURGICAL ASSOCIATION.

THE PRESIDENT'S ADDRESS.

Delivered September 18, 1888.

THE RELATION OF SOCIAL LIFE TO SURGICAL DISEASE.

BY D. HAYES AGNEW, M.D.,
RHEA BARTON PROFESSOR OF SURGERY IN UNIVERSITY OF PENNSYLVANIA

THERE is no tyranny more exacting or despotic than that exercised by the conventionalities which govern our living. All stages of life from infancy to old age are under its domination. It dictates the education, the manners, the walk, the dress, the forms of speech—in fine, the whole being. Beyond all contradiction the behests of fashion are vastly more influential in governing public conduct than any arguments drawn from the teachings of structure and function. As a rule, when the conflict is between taste and reason, the victory will be on the side of taste. In nothing is this more forcibly displayed than in the apparel used to protect the body.

It is not an agreeable task to peer into the wardrobes or dressing-rooms of our fair countrywomen. I have no special taste for exploring museums or bizarre collections. Indeed, without a key to interpret the curious and ingenious mechanisms for clothing the form divine, such an exploration would be like an archæologist attempting Egyptology ignorant of cuneiform inscriptions. I have, however, some knowledge of human anatomy in its broadest sense, and when I look upon the masterpieces of the human form, whether in marble or on canvas, a Belvidere Apollo or a Venus de Medici, and contrast these with the dressed-out specimens of modern women, I am forced to admiration; not so much at the amazing ingenuity displayed in concealing the divinely appointed form, as at the plasticity and patient submission of mortal clay under the despotism of a conventional inquisition. Were these processes of mutilation and abnormality harmless, did the body consist of a mere mass of protoplasm capable, under the application of certain stimuli, of assuming normally protean shapes, the subject might be passed over with the feeling of a naturalist, but this is not so. These violations of the laws of structure bring with them serious penal inflictions, which, did they terminate with the original offender, might be dismissed with a sentiment of pity, but projecting, as they do, their baneful consequences to successors they become proper subjects for criticism.

Let me name a few examples as illustrative of my subject. For some time the profession has been speculating on the causation of

NASAL AND POST-NASAL CATARRH,

with its accompanying auditory defects, the growing frequency of which cannot have escaped general observation. Doubtless no single agency will explain the presence among us of this unpleasant disease, yet there are facts connected with this affection which to me are very suggestive. I cannot recall an instance in which I have met with the disease among females belonging to the Society of Friends, Dunkards, or Mennonites. If this, on more extended observation, proves to be true, may not the head-dress peculiar to these people be accepted

in explanation of their exemption. The bonnet which at one time overshadowed the entire head, as all know, has been gradually shrinking in its dimensions, until it has become a mere shadow of its former self, and offers no protection whatever to the head. As a substitute, I would not insist upon the quaint headgear of the Friend, though I believe that any modification which will protect this part of the body will lessen the tendency to catarrhal inflammation of the naso-pharyngeal mucous membrane.

MUSCULAR RESTRAINT.

A legion of physical imperfections arises from muscular restraint. Among these may be mentioned weak ankles, narrow or contracted chests, round shoulders, projecting scapulæ and lateral curvature of the spine. The foolish concession to appearance and the unwise partiality of parents for enforced systems of education, the demands of which bear no just proportion to the capacity of the infantile mind, constitute the initial or determining force of these physical imperfections. In many cases the weak ankles of children, characterized by eversion of the feet, thus allowing the superincumbent weight of the body to be transmitted to the latter, inside of the proper centre of support, is largely chargeable to the miserable practice of placing on the little ones, long before they are able to walk, boots tightly laced up the limb some distance above the ankles. The confinement of the flexor and extensor muscles by this constriction prevents that free play of movement which reacts so favorably on all the elements of an articulation, and that, too, at a time when the growing forces are at full tide, so that when the time arrives for standing and walking, the muscles are unequal to the firm support of the joint. The consequence of this feebleness is soon seen in the turning outward of the feet, throwing the strain on the internal lateral ligaments, which in turn become elongated through growth, and thus the defect becomes established, but the evil does not terminate here. The calcaneo-cuboid and the astragalo-scaphoid ligaments, losing the proper support of the tendon of the posterior tibial muscle, under the abnormal tension begin to yield and to the deformity of eversion is added that of "flat-foot." That the above is not a mere hypothetical explanation of the ankle defects I have many times verified by finding the threatening symptoms disappear after liberating the imprisoned muscles and subjecting the enfeebled parts to a judicious massage. Under no circumstances, as is too often the case, should instrumental apparatus be applied, unless in cases in which, from neglect, the deformity is thoroughly established and is progressive.

Take another deformity, that of bow-legs. On the earliest signs of the unsightly curve, the limb is too often trammelled with irons, and the growth of the muscles arrested, when it is well known that if manual force be systematically applied two or three times a day the limbs will gradually assume their typical form.

Again, in further illustration of our general text, take, as an example, a child who for one long or two short sessions, for six days of the week, sits over the study desk, compelled to assume a position in which, from the inclination of the body, the shoulders fall forward, the head being supported, most probably, on the elbows and hands. In such a posture, the great serratus and pectoralis major and minor muscles are in a state of relaxation, while the erector spinæ and trapezei muscles are in a state of tension. This change in the position of the shoulders gives the scapulæ over, without antagonism or resistance, to the action of the rhomboidei and the levatores angulæ muscles, which, acting conjointly, cause that projection of the lower angle of the shoulder-blades, which the older anatomists termed "scapulæ alatæ." To all this must be added the very important factor of four to six hours in the school-room, and two hours, at least, of home preparation for the following day's recitations, during which time the respiratory functions having been reduced to a minimum of activity, the muscles of the chest are comparatively passive and aëration of the blood tardy. Certainly no combination of conditions could be better devised for forming contracted chests and round shoulders. It is not long before the watchful eye of the mother detects the change in the figure of her child. She will probably discover this and take alarm, even when the pale face, the languid air, and the capricious appetite of the child cause no anxiety; and then comes the second act in the drama of physical deterioration, namely, a resort to shoulder braces and stays, in order to accomplish that which the muscles should be taught to do without restraint or incumbrance.

LATERAL CURVATURE.

While it is true that lateral curvature of the spine depends upon causes both central and peripheral, yet in no small number the deformity is clearly attributable to influences of a social nature. The young column, by reason of the non-union of the epiphysis and diaphyses, and the supple character of its ligaments, is extremely flexible. Whatever, therefore, destroys the muscular equipoise, however inconsiderable the force, if persistently repeated, changes the centre of gravity and develops primary and compensating curves. For six months in the year, any fine morning, groups of young children may be seen plodding along our streets with a miniature library of books suspended from one shoulder. To the already preponderating scale of the balance, add the additional factor, a probably badly arranged light, compelling these little *savants* to assume a lateral inclination of the body in order to obtain the necessary illumination of the subjects of the study, and you have all of the conditions necessary for perpetuating the lateral deformity. "Just as the twig is bent, the tree's inclined." As in the case of round shoulders, so here, in order to prop up the falling column, instrumental contrivances are immediately called into requisition. The body is encased in a formidable coat of mail, to be followed by muscular atrophy and permanent distortion of one of the otherwise most beautiful pieces of mechanism in the human frame. It is true that in most educational institutions for the young, provisions are made for physical culture, and these are in some measure antidotal to the evils complained of, but, in my judgment, do not at all compensate for that free unstudied romp in the open air, untrammelled by the hard and fast rules of calisthenics, so fascinating to the young child. Nor does the evil end here. While the forcing process, which is to stimulate the mental powers far beyond the real capacity of the immature and growing brain to receive, is in progress, another is inaugurated, which is to qualify, especially the female child, to acquit herself with distinction when the

time arrives for entering the great world of society, or, as Thomas Brown would style it, "for the frivolous work of polished idleness." The gait and carriage must be reduced to prescribed rules, the voice toned down to a drawl or trained to move like a mountain torrent. The muscular apparatus of the face must be taught to express, not the spontaneous and natural outflow of feeling which wells up unbidden from the magic chamber of the heart, but rather to produce an effect; and so this work of transformation goes on until it culminates in the full-blown society girl. Is it any wonder that, under such a scheme of education, conducted throughout by a studied disregard of both the physical and mental constitution, and exercising, as it does, such tremendous drafts on the nervous system, that the world is becoming filled with a class of flat-breasted, spindle-limbed young women, unfitted for the varied and responsible functions of womanhood; qualifications, too, which, under a different regimen, and directed into proper channels, would exert a most potential influence on all the great social and moral problems of the age?

While thus plainspoken on the frivolous methods of living, I do not wish to be understood as being unfriendly to the highest cultivation of the mental and physical powers, if conducted on lines in harmony with the organization, nor to any technique which may conduce to personal grace or elegance of manners, so that the manly or womanly personality of the individual be not sacrificed to the Moloch of sentiment and sham. Indeed, indifference to these things is inexcusable in either man or woman as not only lessening their influence in the world, but, in many respects, disqualifying them for the highest discharge of the duties of modern life. Valuable as may be the unpolished diamond, yet it is only after the wheel of the lapidary has worn away the dull incrustations that its true brilliancy is revealed and the gem is fitted to adorn the brow or the breast of beauty.

BODILY CONSTRICTION.

In the further discussion of my subject, I may next notice the evils of visceral displacement and pressure consequent on abdominal constriction. Whatever may be said in regard to Greek and Roman life, the infinite care which these people displayed in developing and maintaining the very best type of the human form, is worthy of admiration. The Ionic "cheton," spoken of by Attic writers, and so often represented in the bronzes of Herculaneum, while it would not exactly satisfy the modern idea of dress, was, at least, free from the charge of interfering with the contour of the human figure. The painters and sculptors of those classic days were reverent students of nature. Their delineations were true to life. Their works furnish us with no hour-glass contractions of the human body. The constriction of the waist operates injuriously on both the supra- and infra- diaphragmatic organs. Any force acting on the base of the thorax and preventing the expansion of its walls, concentrates the function of respiration, which should be general on the apices of the lungs; and hence, under these circumstances, the movements of breathing are, for the most part, confined to the summit of the chest. As the initial seat of tuberculosis is located at the upper part of the lungs, may not the inordinate work entailed on these parts by constriction, have some part in hastening such deposits in the female when the predisposition exists? It is this forcing inward of the costal border of the thorax which causes the groove on the anterior surface of the liver, so familiar to anatomists. This pressure cannot fail to interfere with the descent of the diaphragm and with the functions of the gall-bladder and duodenum, and exercises no small degree of influence in favoring the formation of biliary calculi, females being peculiarly prone to such concretions. The extent to which the liver may be damaged by extreme constriction of the waist, is well illustrated by a case quite recently reported in the *British Medical Journal*, in which a considerable portion of the left lobe of the liver had been separated from the right, the two being connected only by a band of connective tissue, which enabled the operator to remove the detached mass without difficulty.

The evil effects of this constriction on the viscera of the abdomen and pelvis is most strikingly witnessed in the embarrassed portal circulation, in the different uterine displacements, elongation of ligaments, displaced ovaries, tubal inflammations, hemorrhoids, hernia and other morbid conditions which either prevent or disqualify the woman for the exercise of those functions of maternity, and which, in addition, through reflex influences, entail a host of functional disorders reaching into every avenue of the body, and invading both the mental and moral constitution of the victim. So prolific have these infirmities become that a new department of surgery has been organized for their special management. To what, if not to social causes, can these morbid changes of structure in the pelvic organs, especially of the uterus and its appendages, be attributed? Why should laceration of the cervix uteri be so common an accident? Labor is a natural process, and ought not, under ordinary circumstances, to be attended by lesion of uterine tissue. I can conceive of no agency more likely to induce that muscular degeneration which predisposes to this accident, than the modes and methods of modern living, especially among the inhabitants of great cities. In the expression "modern living," much is embraced. It includes culinary pharmacy, overfeeding and drinking, insufficient or injudicious exercise, improperly heated apartments and a disproportion between the hours of exercise and rest.

Contrast, if you will, the muscles of the hardy, country housewife, who, bearing the cares and responsibilities of a dependent family, bustles about the live-long day indoors and out-of-doors, eats with a relish her plain and simple fare, repairs at reasonable hours to bed, and sleeps the sleep of the beloved, undisturbed by dyspeptic night-mares, and rising with the golden dawn, resumes the round of domestic toil with a clear head and supple limbs; I say, contrast this type of a class with that of another, the woman born to luxury and ease whose capricious and exacting taste taxes the art of the professional caterer, who drags out the morning hours toying with some crazy piece of embroidery or trashy novel, lunches at one, rides out in the afternoon for an airing of two or three hours, returns to a dinner of five or six courses at seven, completes the evening at the opera, the theatre or the assembly, and coming home after midnight, crawls into bed weary and exhausted in body and mind, only to rise with the best hours of the morning gone, for another day of aimless routine life.

Can it be doubted that in the first case, with a digestion unimpaired, with the products of textural change consumed by functional activity and eliminated through the proper emunctories, the woman should possess a vital resistance and a tone of tissue altogether superior to that of the other, whose habits of living must necessarily favor their faulty metamorphosis?

To these same agencies must be attributed that brood of nervous and hysterical evils, for the relief of which the gynecologist too often, I fear, invades the domain of womanhood, around which her whole sexual nature revolves, and which, save only in the direst extremity, should be sacred against all operative intrusion.

LATE MARRIAGES

constitute another social evil, the penal inflictions of which involve both sexes alike. Pride and luxury determine long engagements or deferred proposals. Marriage, it is believed, necessarily involves an establishment, a display, a retinue of servitors. The good old notion of two souls being united in wedlock for the purpose of being mutual helpmates and patiently, together, working up from modest beginnings to affluence, seems to be entirely at variance with the modern idea of this relation. In the meantime the young man is betrayed into unlawful sources of gratification, alike destructive to moral and physical purity, the pollution of which incontinence is often subsequently communicated to and perpetuated in wife and offspring. I would not dare to say how many cases of this nature have been entrusted to my professional confidence, though I doubt not my experience does not differ from that of many of my professional brethren whom I address. It is under such circumstances that many of those infective inflammations of the Fallopian tubes, as salpingitis and pyosalpinx, arise, which entail the most serious deterioration of health.

THE FOOT AND THE SHOE.

It may be thought by some persons that the subject of the foot and the shoe is not of sufficient dignity to appear in a public address. The Romans and the Greeks thought differently. The literature of both people is full of references to the shoe worn by both sexes. So important, indeed, are the feet to the well-being of the body that whatever impairs their usefulness, either for support or locomotion, becomes a positive calamity. Nothing can be more unlike the human foot than the modern shoe. Let any one leave the impress of his or her foot in the wet sand of the seashore, and then place alongside of the imprint a fashionable shoe; that the two were ever intended for each other would scarcely strike a child of the forests. The North American Indian entertains juster notions about clothing this portion of his body than does the civilized denizen of New York or Philadelphia. Compare the moccasin with the shoe of the city belle. Compare the *σανδαλον* or the *περσικαι* of Pollux and of Aristophanes with the same, and we shall see that the savage and the polished Greek alike understood the value of sound feet in the race of life. It is the imperfect adaptation of the shoe to the foot which constitutes the fruitful source of tired ankles, corns, bunions, over-lapping of the toes, and ingrowing nails. Some idea may be formed of the magnitude of the evil from the fact that of eight hundred patients under the care of a prominent chiropodist of Philadelphia, the great majority of the defects were entirely attributable to the high heels and the contracted toes of the shoes. Especially do these physical encumbrances arising from a blind submission to social laws operate disadvantageously to our fair women at the beginning of the new dispensation requiring both muscles and brains, and when her friends propose to sweep away all the old traditions and claim for her the earth with all its masculine employments.

GAMES AND AMUSEMENTS

which in themselves are proper and praiseworthy, too often become developed into a craze, working both moral and physical mischief. Professor Leuf, himself a professional in the national game of base-ball, has described the "pitcher's arm" a condition of over-taxed function, and one in which all the anatomical elements of the upper arm are involved. There is also the tennis arm, and the swollen supersensitive prostate of the bicyclist, both due to the abuse of popular amusements.

DEFECTS OF REFRACTION,

or visual defects constitute another class of affections fairly attributable, in many instances, to social influences. The number of children which may be seen in our streets any day wearing glasses, has become a matter of common observation. It is far from being probable that the most exquisite piece of mechanism, the human eye, came from the Divine Artificer, imperfect. Because eyes are young, it does not follow that they are thereby better fitted to sustain prolonged use. Just the reverse is true, and it is high time that parents and educators begin to recognize the fact. The power of the eyes for continued use, like that of other organs of the body, is one of gradation. It moves in the general procession and strengthens with the advance in life, until development has attained it zenith. Not only so, but the eye being a part of the body it must suffer or rejoice through the operation of general causes. A bone may have its normal curves changed, a tendon may slip from its appointed groove, or a bloodvessel be destroyed and yet very little disability be realized, but the eye is made up of such extremely delicate structures, and acts according to fixed physical laws, that not the slighest alteration of a curve, or the mobility or density of its media, can occur without great vitiation of function. To exact, therefore, long hours of study from children of a tender age, involves a degree of functional strain altogether disproportionate to the structural resources of the organ and, by disturbing the orderly processes of nutrition, gives rise to hypermetropia, asthenopia, astigmatism and its companion, headache. That the picture is not too highly colored, or the sensation overstrained, we have only to contrast the children born and reared in those portions of the country not too much dominated by the methods of modern civilization, and who rarely demand a resort to artificial aids to provide for abnormalities of vision. The only remedy for the evil where infantile scholarship is insisted upon, is the Kindergarten, or object system, the most natural and effective plan of impressing the young mind.

RENAL DISEASE.

Is there any reasonable explanation drawn from sources of a social nature for the great frequency of these renal disorders, which come more particularly under the care of the surgeon, as crystalline deposits and calculi? For

maintaining the general health at the highest physiological standard, a proper quality of food and the proper disposal of tissue waste are essential conditions. Along with wealth and luxury come the abuses of the table. Americans are fast becoming a nation of dyspeptics. Our country is so rich in the products of every zone, that nowhere else in the world can you find such a variety of foods, animal and vegetable. These foods manipulated in a thousand ways, by the subtle art of the professional cook, almost necessarily betray one into excess, and also create the desire for wine and other alcoholic beverages to aid the stomach in disposing of its plethoric supply.

In great cities, which furnish relatively the largest number of cases of renal disease, affecting preëminently the mercantile and sedentary classes, we find just the conditions favorable to their development. The competitions of trade keep the merchant always at white heat. Time is golden, and the street car and other means of conveyance annihilate distance, and the ride is substituted for the needful walk. A hasty lunch at the most convenient restaurant satisfies the inner man until the business of the day is closed, when, weary and worn, he is driven to his home to partake of a course dinner, the balance of the evening to be spent on the lounge with the evening paper, or the latest periodical. To the literary man the fascinations of the study and the library charm him away, with their siren voices, from the fields and the highways, until bodily exercise grows distasteful and repugnant. In the meantime there has been no provision made for the waste or tissue metamorphoses of the body through that great agency, exercise. These accumulate in the blood, the internal eliminating organs, of which the kidneys are chief, are overtaxed and then follow the evils of malassimilation and of excretion, in the form of urates and oxalates, often resulting in the formation of calculi.

In conclusion, may we ever hope for a time when the race will realize that these bodies which we wear, which God has so highly honored by his own incarnation, are sacred temples to be kept in harmony with recognized physical laws, and not to be made instruments of mere animal gratification.

ORIGINAL ARTICLES.

A CASE OF CÆSAREAN SECTION.[1]

BY HOWARD A. KELLY, M.D.,

ASSOCIATE PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF PENNSYLVANIA.

IT has been my good fortune to operate successfully upon two cases of Cæsarean section in this city, on April 17th and May 30th of this year, the indications being, respectively, absolute and relative.

While, in the case of the absolute indication, no possible discussion can arise as to the advisability of operation, especially since the publication by Dr. R. P. Harris, of the wonderful results following the introduction of the accurate method of suturing introduced by Sänger; as to the relative indication there is still abundant room for careful discussion, and its consideration would be beyond the scope of the present paper. The writer hopes, however, at no distant day, to present the second case as a basis of a full consideration of this very important topic. The great work of Dr. F. Caruso, upon Cæsarean section, in preparation in the Italian language, will be of the utmost value in settling this question within its proper limits.

CASE. *History.*—Mrs. J., a patient of Dr. A. B. Ireland, a slight, delicate American, four feet six inches in height, twenty-five years old, was at full term on April 3d, when she was taken with labor pains; she went on some days with irregular pains, until they finally became so strong that she sent for her physician, Dr. Ireland, on the 8th, who stayed with her from nine o'clock in the morning until four in the afternoon, returning again in the evening, feeling sure that, from the character of the pains, her strong straining, bearing-down efforts, the termination could not be far distant. On the day following this visit she had one marked and two slight epileptic seizures. From the date of this first visit she remained in her bed until delivered by Cæsarean section. She suffered continuously from distressing, bearing-down sensations, with remissions of hard labor pains, resembling those of the later stages of labor. The midwife, who cared for her under Dr. Ireland's direction, gave an excellent circumstantial account of her condition throughout this period, stating that in her fifty-one years of experience she had never seen a woman in such strong labor pains. In spite of the time she had been in labor and the efforts she had made, the os remained very small, and the cervix rigid. Dr. Ireland made careful, but unsuccessful attempts to effect a manual dilatation. The waters ruptured on the tenth day.

On Monday evening, the thirteenth day, at eight o'clock, all pains ceased, suddenly returning on Tuesday, when her expression was one of marked collapse, and she was too weak to give expression to her distress. Dr. Ireland called Dr. A. A. Starck in consultation. They decided that Cæsarean section was the only possible means of rescue, and sent for me with an accurate statement of her condition. I had the good fortune to have at my house at the time Dr. Robert P. Harris, and Prof. Gardner, of Montreal, who accompanied me.

Dr. Robb and the matron of my hospital, Miss Little, assisted me in the operation. The matron made all necessary preparations in a few minutes, and no time was lost in reaching the patient, who was found profoundly collapsed, with a pulse of 142, a tympanitic abdomen, the uterus prominently vaulting the anterior wall. The pelvic measurements were: Sp. i. 19 cm., cr. i. 25 cm., d. B. 15.

The tissues within the pelvis were found to be œdematous, hard, and hot, and it was impossible to recognize special structures, with the exception of the hard, infiltrated cervix; the pelvis being literally choked with the hard, unyielding mass, above which lay the child's head, which it was impossible to reach. The rapid, feeble tones of the child's

[1] Read at the meeting of the Philadelphia Obstetrical Society, September 6, 1888.

heart showed that it was still living. The patient was examined carefully by both Doctors Harris and Gardner, who unhesitatingly concurred with the views of Drs. Ireland and Starck. The decision was: Cæsarean section indicated, prognosis unfavorable. The patient was at once etherized. The operation was conducted with thoroughly antiseptic precautions, with the exception of disinfection of the room and the neighborhood—the patient living in a frame house in a densely crowded section of the city. Minuter details from the etherization to the final dressing will not be dwelt upon.

Operation.—The time occupied from the beginning of the operation to the last suture in the abdominal wall was thirty-five minutes. After shaving, washing, and thoroughly disinfecting the abdominal wall with a bichloride solution, the field of operation was hemmed in on all sides by cloths wrung out of a five-pro mille solution. The instruments and hands of the operators, and the parts of the patient involved in operating, came in contact with these cloths, and with nothing else in the room. An incision seven inches in length, extending above and below the umbilicus, was made in the median line, and the uterus delivered through it; a rubber ligature was thrown around the cervix provisionally, and a large cloth laid behind the uterus, covering the incision and retaining the intestines. An incision was now made in the uterus near the fundus extending down toward the cervix, which cut across the placenta at its centre (*plac. præv. centr. Cæsar*). Great care was taken not to cut the placental vessels. The placenta was separated readily, and the nearest presenting part caught, proving to be the leg of the child lying in the first position. The child was delivered, membranes and all up to the head, which was firmly wedged at the superior strait, requiring almost a minute to free it, accomplished by inserting the fingers in the mouth and making a pair of forceps of the hands.

Prof. Gardner took possession of the child, which he resuscitated with difficulty to a condition of feeble vitality after persevering in his exertions for half an hour, when it gave its first cry. The placenta and decidua came away with the child. The appearance of the uterus was healthy. The uterine wound was closed by twelve deep and twelve superficial silk sutures, introduced as prescribed by Sänger, of Leipzig. The cloth and the constriction tube, which lay loosely around the neck of the uterus, were removed, and the contracted uterus dropped into the abdominal cavity, which was clean and free from blood. The external incision was closed by seventeen deep and twelve superficial sutures, the wound dressed, and the patient returned to bed.

Up to this time the case is an interesting one on account of the peculiarity of the indication, being one which might arise in a normal pelvis, labor being obstructed by abnormality in the fœtus; the indication here was similar in character to that presented by tumors obstructing the pelvis. Consideration for the life of the child, after such prolonged and severe labor, was not a factor in the decision. Had the child been dead it could have been delivered in no other way.

The after-history presents some points of remarkable interest; on the day following the operation she suffered much from tympany, nausea and vomiting—a continuation of her previous condition. Her pulse was 144, and the temperature 99¾°. Upon taking Epsom salts in concentrated solution, followed by the citrate of magnesia, she had a very large movement, filling a bed-pan. The next morning, pulse was 88 and the temperature normal, where it stayed until the tissues in the vagina began to break down. She took nourishment well from the first, improved at once in appearance, and passed urine voluntarily from the second day up to the secondary period of disturbance from the œdematous pelvic tissues. The child, which was small and wizened, became jaundiced on the third day, dying at the end of a week.

She complained of much pain on the 21st, when all the stitches in the abdominal wall were removed, letting out some dark, grumous pus just below the navel, giving immediate relief. I found, also, that in the pocket in which the child's head had lain, above the undilated portion of the cervix, and below the contraction ring—that is, in the upper part of the lower uterine segment, there was a large accumulation of clots. These I carefully removed, keeping the whole tract clean by repeated douches. The abdominal incision broke down in its upper part, extending downward, and showed at one point the anterior wall of the uterus adherent to the abdominal wall. The infection which, starting in the inflamed vaginal tissues, extended upward, developed for two days a condition of physometra, which disappeared as soon as the opening into the uterus was visible per abdomen, when the whole tract was irrigated from above downward. The infravaginal cervix sloughed away, a large mass crackling with air vesicles, and, with the rapid discharge of all débris, she passed through a period of great danger from septic absorption, with but the slightest symptoms of discomfort.

The note of the 27th, ten days after the operation, states, "patient looks and feels perfectly well, has a bright, happy expression. Pulse 72, temperature normal. Natural movement. Slight, thin discharge from abdominal wound, which is filling up with abundant healthy granulations." Four days later she had a chill, followed by a mild phlebitis, from which she recovered rapidly. I have not seen her since my return from Europe, but Dr. Harris tells me she is well, only needing that the narrow cicatricial cervix be dilated, to allow her to menstruate per vaginam instead of per abdomen.

I am indebted to Dr. Harris for some valuable statistical information, which I shall present in a more formal paper at a future meeting. This is the ninth case of Cæsarean section with preservation of the uterus, performed in Philadelphia. The last successful case was that of Prof. Gibson, of the University of Pennsylvania, fifty-one years ago. The cases operated upon from that time to the present were, almost without exception, received in a condition in the highest degree unsatisfactory to the operator.

In outline the following features appear remark

able. The length of time the patient was in labor—being fourteen days. The pulse at the time of the operation was 142. The agglutination of the uterus and anterior abdominal wall, as observed in Prof. Gibson's and other cases, which in this case prevented general infection of the peritoneum. The remarkable pocket for discharge formed below the contraction ring and above the undilated portio vaginalis.

An important factor, I think, in determining her recovery was that, without undue haste, by quick work, and having all necessities within easy reach, I was able to complete the operation in thirty-five minutes. I have omitted most of the details which are usual in these cases, but cannot close without a tribute to the care and faithfulness of the physicians who visited her during her convalescence, doing often the work belonging to a nurse. Those who have anxiously watched bad surgical cases, sacrificing every personal inclination and convenience while the patient's recovery was a question, will appreciate how much is implied.

MEDICAL PROGRESS.

Cocaine for Pruritus.—Conceiving the iodoform dermatitis mostly the result of the scratching induced by itching—that is, that iodoform only gives rise to itching and inflammation of a moderate degree, GEYER (*Pest. Med. Chir. Pr.*, No. 31) has successfully used cocaine in this affection. As soon as the irritation is perceived the part is brushed two or three times with a ten to fifteen per cent. solution of hydrochlorate of cocaine. With the cessation of the itching the dermatitis also disappeared—that is, it did not occur. In case the dermatitis had attained to some degree, so that vesicles already existed, cocaine checked the itching and the progress of the inflammation, but it failed to hasten the retrogression of the vesicles. Geyer has also with success used cocaine in other itching, cutaneous affections; for instance, in the case of a woman, in whom, at the menstrual period, a circumscribed, urticaria-like, intensely irritating eruption appeared at various parts, from its severity disturbing sleep. The itching was diminished by applications of cocaine, and subsequently, upon timely application, entirely relieved. Finally, Geyer applies cocaine for the itching of urticaria.—*Wien. medizin. Presse*, No. 34, 1888.

Salicylic Acid in Metrorrhagia.—FELICI (*Gazetta degli Ospitali*) reports two instances of surprising results from the use of salicylic acid in metrorrhagia. In the one, the hemorrhage was due to carcinoma and resisted all treatment. By means of a carbolated tampon, moistened with a solution of salicylic acid, Felici was enabled to check the bleeding in a few minutes. The second case was that of a woman, who was taken with such severe hemorrhage during the menopause that collapse occurred. After the ordinary remedies had been fruitlessly applied, Felici tamponed the uterine cavity with a cotton plug, moistened with a solution of salicylic acid, whereupon the bleeding permanently ceased.—*Wiener medizin. Presse*, No. 34, 1888.

Uterine Tympanites relieved by Creolin Irrigation.—BRAUN (*Wiener medizin. Presse*, No. 34, 1888) reports that in all cases in which creolin was used at the Cracow clinic for gynecology and obstetrics the result was entirely satisfactory. Naturally creolin was chosen in preference to corrosive sublimate and carbolic acid in such cases in which danger of intoxication existed. The results were admirable in two cases of uterine tympanites followed upon protracted labor. The first case was that of a multipara, in which the liquor amnii had been evacuated five days before. Tympanitic resonance was manifested over the uterus. After delivery with the forceps, a foul-smelling, gaseous, dirty fluid escaped. Notwithstanding the existing fever, after irrigating the uterine cavity with a two per cent. solution of creolin, three times daily, the trouble was relieved, and in fifteen days the patient was discharged. In the second case there was a shoulder presentation, labor lasting five days, the fœtus was putrid, the temperature 104°, pulse 130. After applying irrigation as already mentioned the septic inflammation of the uterine mucous membrane disappeared.

Treatment of Burns.—WENDE speaks very highly of a dressing for burns, composed of cocaine, four per cent., and lanolin. This mixture should be freshly prepared and the cocaine perfectly pure. It assuages pain immediately and the healing takes place rapidly.—*Journal de Med. de Paris.*

Untoward Action of Sulphonal.—The following case, reported by DR. SCHUREY, in the *Therapeutische Monatshefte* for July, is interesting, as illustrating the untoward action of sulphonal. A patient of sixty-one years, with arterio-sclerosis, suffered with attacks of angina pectoris and insomnia. By the use of amyl nitrite the attacks were aborted and the intervals between them lengthened. The sleeplessness was successfully overcome by the use of amylene hydrate. The patient, after a time, unwilling longer to take the latter, on account of its disagreeable taste, sulphonal was prescribed in doses of thirty grains. The result was surprising. Soon after the ingestion of the drug the attacks of angina pectoris recurred with great frequency; a few minutes after one attack was checked by amyl nitrite another began. This lasted throughout the night. There was no real sleep, but two hours after the administration of the remedy a sort of half slumber, interrupted by frequent attacks, was had. For the next two days the attacks continued with increased violence and frequency. The author cautions against the administration of sulphonal in cases of arterio-sclerosis.—*Wiener medizin. Presse*, July 29, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 22, 1888.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Two years ago the American Surgical Association suggested to its kindred special societies the organization of a Congress of American Physicians and Surgeons. These societies cover all the principal departments of medicine, and their membership, which is elective, includes the best known workers in the various specialties. The idea of their coördination was a happy one, and the plan promptly met with a hearty approval. This week has witnessed the realization of the project in the Joint Meeting of the American Surgical Association, the American Association of Genito-Urinary Surgeons, the American Laryngological Association, the American Climatological Association, the Association of American Physicians, the American Otological Society, the American Ophthalmological Society, the American Neurological Association, the American Dermatological Association, the American Physiological Society, the American Orthopedic Association and the American Gynecological Society.

The twelve special societies met in Congress, and also, preserving their autonomy, have at the same time held their usual annual meetings, as it were as sections of the Congress. The result was all that had been hoped for. The value of the scientific work done by these special societies for years past is well known, and the same high standard was preserved in the proceedings of the Congress, as will be seen on reference to our report of the proceedings.

This initial session has shown that the Congress is held purely in the interests of medical science and its advancement, and that the plan of organization has been so wisely devised that politics, the blight of so many fair projects, is effectually excluded. No executive business, not even the election of officers, is transacted by the Congress. It meets solely to listen to and to discuss scientific papers. Its members are the active clinicians, authors, and teachers of to-day, and the joint discussion by them of the practical problems in medicine and surgery which are pressing upon our attention at present, cannot fail to contribute materially to their solution and to the advancement of our knowlege.

The plan of organization met with cordial approval, and the selection of Dr. Billings as President was regarded as a just tribute to a distinguished member of the profession and a merited recognition of his laborious and unselfish devotion to the cause of medical science and literature.

The social phase of the Congress was a feature which is not without its importance. It served to bring into pleasant personal relationship men in the different departments of medicine, who were well known to one another by reputation, but who, perhaps, otherwise might never have been brought together; and they will hereafter have the advantage of the greatly increased interest which always attaches to the researches, writings, or teachings of those with whom one is personally acquainted. Moreover, in our daily reading, the personal equation is a not unimportant factor in enabling us to estimate correctly the value of scientific contributions. The social arrangements at Washington were, in every respect, admirable. The general dinner on Monday evening, and the receptions on the other evenings, gave the members the fullest opportunity for mutual, social intercourse.

The Congress, in its membership, constituted one of the most notable medical gatherings ever assembled in America. Among its participants were a very large proportion of those who are everywhere recognized as guiding our medical thought and advancing the reputation of American medicine. The brilliancy of the gathering, too, was heightened by the presence and participation in the proceedings of a number of eminent *confrères* from across the water.

The Congress will meet triennially at Washington, and the second session will be held in the autumn of 1891.

THE PRESIDENT'S ADDRESS.

FOR his address, as President of the Congress of American Physicians and Surgeons, DR. BILLINGS chose a novel and interesting subject, one which, so far as we know, has not before been dealt with in so exhaustive a manner. Naturally enough, as Curator of the Army Medical Museum, which has so recently been placed in suitable quarters, he felt the occasion appropriate to tell the story of its origin and growth, to explain its wants, and to say something upon the advantages of collections to medical schools and to the profession.

When a physician in a strange city wishes to estimate the scientific standard of its profession, let him visit its medical libraries and museums. They are the indices of progress and of work, as infallible as crowded docks and busy streets are of commercial enterprise. It means that there are men in that town, "whose labor and thought have not been confined to their own interests," but who have been zealous in those things which, after all, make a profession great. And visitors to this country when they inspect the beautiful collection at Washington, see a monument not unworthy of the Army Medical Department, and of the profession at large. It is a matter of pride and congratulation that within the short space of twenty-six years the museum has reached such proportions that it now ranks as one of the eight largest in the world. And let us not forget in these congratulations the little Circular No. 2, issued on May 21, 1862, by Surgeon-General W. A. Hammond, to whom the great honor belongs of starting the work.

The elaborate review of the museums of this country and of Europe is not only of value in itself as a record of unusual interest, but it will arouse, we trust, our medical schools to a proper sense of the value of collections as a means of instruction. With the exception of half a dozen of the larger colleges, very few of the teaching bodies make adequate provision for securing and preserving specimens. One great difficulty is the expense, but harder still is it to obtain men with the necessary enthusiasm. The Warrens, Wister and Horner, Mütter and James R. Wood, whose names are attached to some of the most important medical museums of the country, were great teachers, practical men, who knew the value of specimens in illustrating lectures. Would that they had more imitators in the present day and generation.

The capabilities and needs of the collection at Washington are now plainly before the profession. Evidently it is the desire of the Surgeon-General and Dr. Billings to have such an exhibition at Washington, that a physician from any part of the country, visiting the capital, can have an opportunity of seeing a complete array of physiological, anatomical, surgical, and other apparatus and specimens. Everything, for example, from a plethysmograph to a percuteur, and from an elaborate dissection of the solar plexus to a well-displayed series of anomalies of the epigastric artery. In time, we have no doubt that the museum will be in this way as much used as the library as a means of education. Meanwhile, every physician throughout the country is called upon to do his share in the work and to aid in making the collection such as a great profession and a great nation have a right to demand.

THE YELLOW FEVER EPIDEMIC.

THIRTY years ago the opinion prevailed in several of our southern seaports that yellow fever was a necessary evil, an endemic disease due to climatic causes, in connection, perhaps, with local insanitary conditions, and, consequently, that it was not to be excluded by any quarantine restrictions. Now we know better and have ample data to demonstrate that this pestilential disease is nowhere endemic on our shores. Having this knowledge, the question of responsibility for the epidemic prevalence of the disease at once presents itself when we see repeated at Jacksonville in 1888 the heartrending events which marked the progress of this disease in 1878 in the States of Alabama, Louisiana, Mississippi, and Tennessee.

History repeats itself in these yellow fever epidemics; the reluctance to admit that the enemy has obtained a foothold; the concealment of early cases and the attempt to call them by some other name; the vain hope that the disease will not extend—that there will not be much of a shower after all; the mistaken reliance upon not being afraid, or upon the burning of tar barrels and the firing of cannon; the assertion that the early victims died from their own fault—from fear, imprudence, or something else than the malignant poison which already infects the atmosphere; the sudden terror and "stampede" when the nature of the disease is generally recognized and a few prominent citizens have become its victims; the attempt to effect a general exodus of the population when other communities are terrified and when sanitary cordons and shotgun quarantines

are the order of the day; all this is an old story to those who are familiar with the history of yellow fever epidemics in the United States.

But we had hoped that it was so old and so familiar that there would be no repetition of the sad, disgraceful spectacle. For there can be no doubt that, in the present state of knowledge, such epidemics are inexcusable. Some one is responsible for them. Or, rather, the responsibility rests somewhere, but under our present system, or want of system, of sanitary administration it is often difficult to say just where.

An epidemic on our soil requires the transportation of an exotic germ to a favorable location, and, although we may not know the precise form or the specific characters of this germ, we do know that in a vast majority of the cases new infected centres are established by those who fall sick of the disease in localities more or less distant from the place where they received the morbific agent into their system.

The indications for sanitary prophylaxis are, therefore, apparent: the exclusion of the exotic germ; isolation of the sick; disinfection of excreta and of all articles which have been in contact with the sick, and of their apartments and immediate surroundings; sanitary police of infected or exposed localities. But, to accomplish the end in view, these measures must be carried out promptly and intelligently in accordance with the knowledge which has been acquired as a result of dear-bought experience in previous epidemics, and of the labors of those who have determined the value of disinfectants by scientific methods.

Has this been done in Florida? Were the proper steps taken to exclude the exotic germ in the first instance, to isolate the sick and disinfect excreta, clothing, etc., when it was known that the disease had obtained a foothold at Tampa, Plant City, and, finally, at Jacksonville? Who is responsible for the failure to stamp out the disease in the early spring, when it was well known that it had survived the winter on the soil of Florida and, with the recurrence of warm weather, was certain to become epidemic, if any reliance could be placed upon previous experience?

Wherever the disease becomes established, the well-known principle of depopulation of the infected locality should be promptly and efficiently carried out. To attempt to shut in the population of infected localities by sanitary cordons and shotgun quarantines is a practice which is generally condemned by enlightened sanitarians, and its uselessness was affirmed by the International Sanitary Conference of Rome (1885), in a proposition which was adopted with but a single dissenting voice.

THE Association of American Anatomists was organized in Washington last Monday, and the following officers were elected: *President*, Dr. Joseph Leidy, of Philadelphia. *Vice-Presidents:* Drs. Frank Baker, of Washington; F. D. Weisse, of New York. *Secretary* and *Treasurer*, Dr. A. H. P. Leuf, of Philadelphia. *Executive Committee:* Drs. Harrison Allen, of Philadelphia; Burt G. Wilder, of Ithaca, N. Y., and A. C. Bernays, of St. Louis.

The American Pediatric Society was likewise organized on the next day by the election of the following officers: *President*, Dr. A. Jacobi, of New York; *Vice-Presidents:* Drs. A. V. Meigs, of Philadelphia; F. Forcheimer, of Cincinnati. *Secretary*, Dr. W. B. Booker, of Baltimore. *Recorder*, Dr. William Perry Watson, of Jersey City. *Council:* Drs. T. L. Latimer, of Baltimore; J. M. Keating, of Philadelphia; J. N. Love, of St. Louis; J. H. Ripley, of New York; S. C. Busey, of Washington; C. P. Putnam, of Boston, and A. D. Blackadar, of Montreal. A constitution was adopted, and the meeting adjourned.

PROF. VON ESMARCH, of Kiel, who came to this country to attend the Congress of American Physicians and Surgeons, will lecture at the University of Pennsylvania this Saturday, at 11 o'clock, and at 12.30 will operate in Prof. Gross's Clinic, at the Jefferson Medical College.

M. DUJARDIN-BEAUMETZ has been sent by the French Government on a mission to Russia, to study its hospitals and methods of medical instruction, and M. Fremy to the United States to study the hospital arrangements for the treatment of tuberculosis.

AT the cemetery at Zurich there is being erected a crematory, the dedication of which will take place in the early fall. On both sides of the main apartment containing the furnace will be constructed niches for urns.

THE Accademia medico-fisica fiorentina has offered a prize of five hundred francs ($100) for the best work upon the surgery of the brain, spinal cord, and contiguous structures. The essay must be written in Italian, French or Latin.

SOCIETY PROCEEDINGS.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

First Triennial Session
Held at Washington, September 18, 19 and 20, 1888.

(Specially reported for The Medical News.)

Tuesday Morning, September 18th.

MEETING FOR ORGANIZATION.

Dr. Pepper, of Philadelphia, the Chairman of the Executive Committee, called the Congress to order at 1 P.M. and spoke as follows:

On behalf of the Executive Committee I have the honor to announce to you, the members of the various special Associations composing the Congress of American Physicians and Surgeons, the manner in which we have discharged the responsible duty entrusted to us.

The present meeting is the result of prolonged deliberations. The development of one special society after another showed the irresistible tendency of the recent progress of medical science. The deep interest which attaches to the meetings of these separate bodies suggested naturally the thought of a conjoint meeting, which would bring together the active workers in allied fields. This thought began to take definite shape as much as four years ago, before the attention of the medical profession became occupied with the preparations for the meeting of the International Medical Congress, which occurred in this city last year. But all action was deferred, in order that there should not be even the semblance of interference with that important meeting. The delay has not been injurious. It has rendered more than ever conspicuous the actual need of an organization to secure the reunion, at stated intervals, of the more active teachers and writers and workers in the leading branches of medical science. Such reunions must be at a locality to which it will be possible to draw such men from all quarters.

In order to produce the best scientific results, it is essential that the members in attendance shall be reasonably limited, and that, as far as possible, the same men shall attend successive meetings. A continuity of intellectual life and activity is thus secured, which increases greatly the benefits derived from these meetings. A large proportion of those interested in the development of such an organization are, as I am myself, warmly attached to the American Medical Association, and determined to exert their influence to maintain and promote the success of this great national organization. All are no less warmly interested in the prosperity of the various special societies to which they severally belong. Your Executive Committee found little difficulty, however, in deciding upon a plan which would avoid even the least interference with the American Medical Association, while, at the same time, it avoided any encroachment upon the independence and autonomy of the special Societies. It is unnecessary to dwell upon the special points which have been embodied in the by-laws which will be immediately submitted to you.

Your committee ventures to hope that these provisions, which are strictly in accord with the terms of the resolutions under which they were appointed, will meet the unanimous approval of the Congress. We have recommended that the sessions shall be triennial, thus leaving to each participating body two intervening independent meetings, at such time and place as may be chosen. We have jealously guarded against the admission of any parliamentary business into the work of the Congress, the functions of which are designed to be absolutely and exclusively scientific. Thus, and thus only, can the sessions of this body be lifted up into and maintained in that high and cool air of learned discourse which best permits the diffusion of truth and the promotion of science. We have no less jealously guarded the independent sovereignty of each participating society. To all their full rights are preserved; to all equal privileges are accorded; upon all the burden of expense, which should always be but a light one, has been laid in equitable distribution. The successive meetings of the Congress will be held in this beautiful city, which every year becomes more accessible, more attractive, and more precious to every citizen of the republic. Nor could we fail to make acknowledgment of the great material advantages we shall enjoy in these meetings here, through the liberal and enlightened policy which places freely at our disposal the admirable facilities of the Medical Department of the Government.

Here, too, your Executive Committee would gladly acknowledge, we have found colleagues in the members of the Committee of Arrangements, to whom, and especially to whose chairman, Dr. S. C. Busey, we desire to return cordial thanks for a zealous and harmonious cooperation which has contributed in very large proportion to the successful inauguration of this new organization.

And lastly, your Executive Committee would report that in the discharge of one of the most important of our duties we have reached the conclusion that the selection of the president of each Congress shall be entrusted to the Executive Committee then in office. Thus will the choice of the most worthy and most representative men of the whole country be insured at the hands of a truly representative body, specially selected by their various societies for their ability and judgment.

The powers you are asked to confide to future executive committees are large, but they will be reposed in safe hands. Each society participating will be stimulated to continuous and lofty effort. Membership in any of these bodies will come to be regarded as more and more an honor, and in time the scientific qualifications of candidates will be more and more strictly scrutinized. Can there be any doubt that if the spirit which has led to the formation of this Congress be maintained and cherished, this new organization will exert a powerful and beneficent influence on the future of medical science?

It remains then only to add that in exerting the privilege of selecting a president for this first Congress of American Physicians and Surgeons, your Executive Committee feel they have been guided to the choice of a man whose admirable personal character, whose high attainments, and whose illustrious services in the cause of literature, of science, and of the entire medical profession, mark him as entitled to this great honor and distinction. It gives me, therefore, the utmost gratification to present to you our president, Dr. John Shaw Billings, and to announce that the Congress of American Physicians and Surgeons is now duly organized.

Dr. Billings then came forward, and in a few words expressed his appreciation of the honor which had been

conferred upon him in his selection for the important position of President of the Congress.

He then read a cablegram of greeting to the Congress just received from Sir Henry Acland, the late president of the Medical Council of Great Britain.

The President then introduced DR. S. C. BUSEY, the Chairman of the Committee of Arrangements, who made an

ADDRESS OF WELCOME.

He welcomed the Congress in behalf of the Committee of Arrangements and of the profession and citizens of Washington. The circumstance of the simultaneous assemblage here to-day of the special medical societies of this country, he said, marked an epoch in the history of the American medical profession. The gratification felt in welcoming them was enhanced, he said, by the presence of the distinguished men from other countries who have come to honor and encourage them.

DR. PEPPER, from the Executive Committee, submitted the following

BY-LAWS,

which were adopted.

1. This organization shall be known as "The Congress of American Physicians and Surgeons."

2. It shall be composed of national Associations for the promotion of medical and allied sciences.

3. It shall hold its sessions triennially in the city of Washington, D. C.

4. The officers of the Congress shall be a President, Vice-President, Secretary, Treasurer, and an Executive Committee.

5. The President shall be elected by the Executive Committee, of which he shall be *ex-officio* a member.

6. The Presidents of the participating societies shall be *ex-officio* the Vice-Presidents of the Congress.

7. The Secretary and Treasurer shall be elected by the Executive Committee. They shall be *ex-officio* members of the Executive Committee.

8. The Executive Committee shall be composed of one member from each participating society, and said members shall be elected by the various societies at the next annual meetings subsequent to the Congress.

It shall be charged with all duties pertaining to the organization of and preparation for the ensuing Congress, including the election of all officers and of a Committee of Arrangements.

It shall superintend the publication of the transactions of the Congress.

9. The expenses of the Congress shall be divided between the participating societies in proportion to their membership.

10. The admission of new Associations to participation in the Congress shall be by unanimous vote of the Executive Committee.

EVENING SESSION.

DR. REGINALD H. FITZ, of Boston, opened the discussion on

INTESTINAL OBSTRUCTION IN ITS MEDICAL AND SURGICAL RELATIONS.

He confined himself to the diagnosis and medical treatment of acute, internal, mechanical varieties of intestinal obstruction. The only causes recognized were strangulation from adhesions, vitelline remains, peritoneal slits, pockets and rings; intussusception, knots and twists; abnormal contents; strictures and tumors. The evidence presented resulted from the analysis of 295 cases collected from medical literature since 1880.

The most constant symptoms of obstruction proved to be pain, vomiting, tympany, and tumor. Stoppage of the bowels was not regarded as the most essential symptom in diagnosis, since frequent, loose stools characterize intussusception and may occur in other varieties of obstruction. Too much attention directed to this symptom leads to erroneous diagnosis, since it is of frequent occurrence in peritonitis, and often results in irrational and injurious treatment.

The physician is called upon to decide whether the given case is one of acute obstruction; then, where its seat and what its cause; and, finally, what is to be done. The evidence showed that the diagnosis is to be made by excluding the various causes of peritonitis. Its seat in the large or small intestine is to be determined by injection, under high pressure, when necessary. The variety is, for most practical purposes, an intussusceptum or a twist of the large intestine, and strangulation or gall-stones of the small intestine. The differential diagnosis depends upon the relative frequency of these varieties, the age of the patient, the antecedent and immediate symptoms. The treatment consists in the attempt to relieve intussusception of the large intestine by forced injections, under anæsthesia and with massage, and to treat obstructing gall-stones by opium, possibly with the aid of laxatives and electricity. All the other varieties of acute obstruction require surgical treatment. The latter is also necessary, on or before the third day, in cases of intussusception not yielding to forced injection, and in gall-stones when the symptoms become urgent.

DR. SENN, of Milwaukee said: The operative treatment of intestinal obstruction is in its infancy. Since laparotomy for other indications has become an established and frequently practised procedure, a number of the bolder and more aggressive surgeons have resorted to direct measures for the relief of intestinal obstruction, but, like all serious operations for otherwise incurable and fatal affections, its general application has met with strong opposition, not only by the laity, but also by the profession. The appalling mortality which has attended the operation in the hands of even the most competent surgeons has been quoted in the discussions on this subject in medical societies as a sufficiently strong argument in favor of non-operative interference. In this regard, the history of laparotomy for intestinal obstruction is only a repetition of the history of ovariotomy.

The mortality of laparotomy for acute intestinal obstruction will be reduced to that of other intraperitoneal operations, and surgeons will recognize the importance of operating early before the patient's strength has been wasted by the disease, and before the parts involved in the operation have undergone irreparable textural changes. The mortality of abdominal section in the treatment of the different forms of intestinal obstruction will always be great because the conditions which have caused the obstruction are often an intrinsic source of danger. In others the removal of the obstruction necessitates an intestinal resection, which in itself is a vastly more serious operation than the removal of an ovarian tumor.

Intestinal obstruction, irrespective of its cause, is always followed by a series of consecutive pathological changes which, independently of the partial or complete interruption of the passage of intestinal contents, tend to destroy life. The dilatation of the intestinal tube on the proximal side of the seat of obstruction may give rise to such a degree of abdominal distention as to destroy life from suspension of important functions by mechanical pressure. In acute obstruction, violent peristalsis on the proximal side of the occlusion causes an increased afflux of blood to the portion of bowel the seat of exaggerated physiological function; which, after cessation of peristaltic action, remains as an intense venous and capillary engorgement. During the paretic stage the bloodvessels in the intestinal wall have lost their support, hence transudation and exudation readily take place into the paravascular tissues, which, combined with the capillary stasis attending this stage of the inflammatory process, results in gangrene. The intestinal wall, in a state of inflammation, becomes permeable to pathological microörganisms which are always present in the intestinal canal, and which, after passing through the entire thickness of its walls, enter the peritoneal cavity and induce septic peritonitis—a frequent immediate cause of death. These facts are cogent reasons for adapting surgical measures in all cases of intestinal obstruction due to mechanical causes as soon as a diagnosis can be made. If this were done, the two greatest sources of immediate danger attending and following laparotomy, shock and septic peritonitis, if not entirely avoided, at least would be less likely to occur, and the tissues the seat of operation would be in a favorable condition for direct treatment and repair.

An abdominal section in the treatment of intestinal obstruction is always necessarily attended by some shock, and it is, therefore, of the utmost importance to perform the operation at a time when the organs of circulation and the nervons system are still in a condition to resist successfully the immediate effects of the operation. Death from septic causes can only be avoided by operating at a time when the intestinal canal, at the seat of obstruction and on its proximal side, is still in a condition capable of resisting infection, and of undergoing a satisfactory process of repair, in case it becomes necessary to incise or resect during the operation. The statistics of operation for intestinal obstruction will improve as soon as we shall be able by improved methods of diagnosis to make an early positive diagnosis, and will adopt in the treatment positive surgical measures before the prospects of a recovery have been rendered improbable, if not impossible, by days and weeks of useless, and more than useless, medication. True intestinal obstruction, whatever its cause may be, is as strictly a surgical affection as strangulated hernia, and remediable only by the same kind of surgical treatment. Physicians should recognize this fact, and should call into counsel a surgeon as soon as a probable diagnosis of intestinal obstruction can be made. To let a patient die of the consequences of a removable cause of obstruction, without an operation, is a reflection upon modern surgery. The difficulties which surround the diagnosis, and the present imperfect technique of the operative procedures in cases of intestinal obstruction, are not only responsible for the heretofore late operations, but also, to a great extent, for the many failures. Ways and means for more accurate diagnosis will have to be devised by more careful clinical observations and by experimental research, while new and improved methods of operation must be devised and their merits safely tested by experiments on animals.

Insufflation of hydrogen gas is a valuable means of diagnosis in locating the seat of obstruction before tympanites has set in, and, therefore, best adapted at a time when most needed—during the early stage of intestinal obstruction. If the colon dilates uniformly from the sigmoid flexure of the cæcum, the obstruction must be sought for higher up in the intestinal canal. The passage of gas through the ileo-cæcal valve rendered incompetent by the distention of the cæcum is always attended by a characteristic gurgling or blowing sound, which is always heard most distinctly by applying the ear or stethoscope over the ileo-cæcal region. Not infrequently the sounds are so loud and distinct that they can be heard at a distance of several feet.

If the gas passes the ilio-cæcal valve under a pressure not in excess of that required to overcome it in a state of health, and if, after inflation, a thorough examination of the ileo-cæcal region by inspection, palpation, and percussion reveals nothing abnormal, the search for the obstruction is continued by inflating the small intestine slowly and making frequent examinations of the abdomen to ascertain the height to which inflation has been made and to study the relative positions of the different abdominal organs. Inflation is also a useful diagnostic resource in locating the obstruction during laparotomy for intestinal obstruction. The intestine below the seat of obstruction is always empty, collapsed, and anæmic as compared with the portion above the obstruction.

When the obstruction is located high up in the intestinal canal and the tympanites is extensive, the empty portion of the small intestine has by compression become displaced, and is often not readily found. In such cases the distention of the bowel from below will indicate to the surgeon at once the location and length of the intestine below the seat of obstruction from below upward. The manipulation of the healthy intact portion of the intestinal canal in search for the obstruction is by far a less hazardous procedure than the handling of the distended portion above the obstruction rendered paretic, exceedingly vascular, and much softened by obstruction.

In cases in which we suspect the presence of a perforation, inflation with hydrogen gas will demonstrate not only its existence, but also its location. Invagination is rare above the ileo-cæcal valve, and location can be determined by inflation with hydrogen gas, and if resorted to early it may prove the means of effecting the mechanical reduction. In ileo-cæcal and colonic invagination slow and persistent distention of the colon with hydrogen gas, with the patient completely under the influence of chloroform, is the safest and most efficient means of effecting reduction, and should always be resorted to whenever these conditions are recognized or even suspected.

MR. DURHAM, of London, desired to express the extreme pleasure he felt in coming here among his American *confrères* and at the hospitable reception he had received at their hands. The subject of intestinal obstruction is one in which he had taken the greatest possible interest. It was possible some of those present might have come across a book entitled *Quain's Dictionary of Medicine*, and if they would look over that book they would

find that the article on intestinal obstruction was written by him. He takes a deep interest in these cases, inasmuch as the life and health, the comfort and prosperity of the patient depend upon a rightful action on the physician's part. Truly he may say there is no class of cases more dangerous, more serious, more urgently calling for surgical treatment than those cases of intestinal obstruction. He agreed with Dr. Senn in one thing, and that is, that the sooner the physician calls in the surgeon the better it is for the patient. He agreed with Dr. Senn, that surgical operation should be performed as soon as the diagnosis is made, but he did not know any class of cases in which the diagnosis is so difficult as in this class of cases. He went further than Dr. Senn and said that cases do occur, from time to time, in which the surgeon is justified in operating before he had made a diagnosis, in order to enable him to make one.

In regard to this question of diagnosis, he said, that if his hearers would recall his article in Quain's *Dictionary*, they would recollect that he had collected several thousand cases. What we should be guided by is not the statistical probabilities but the actual indications of the particular case before us. Every case must be studied and judged upon its own merits and treated according to the indications that present. The chances may be 999 to 1000 in favor of one man and 1 to 1000 in favor of another.

In regard to the treatment of intestinal obstruction, he would say the first thing to do, is to determine the seat of the obstruction. In cases of acute intestinal obstruction, or where there is reason to believe that the obstruction exists in the small intestine, then he believes the proper course of treatment to pursue is to open the abdomen and search for the cause and relieve it as best we can. On the other hand, when the indications are that the obstruction is in the large rather than in the small intestine, there is not the same degree of urgency in a very large proportion of cases. Of course, the procedure to be adopted must depend upon the fact as to the seat and the cause of the obstruction, and here he ventured, with the greatest hesitation, to take issue with Dr. Senn on this point. Dr. Senn said that lumbar colotomy is obsolete. As a matter of fact, it is not obsolete. It is an operation that is performed on the other side of the Atlantic day after day, and will never become obsolete if he can help it. He knew of no operation in surgery, except the simple one of tracheotomy, that affords so much relief and prolongs the patient's life as this. He said that if he himself were the subject of cancer of the rectum, he should most certainly have lumbar colotomy performed.

DR. WM. ORD, of London, said that he supposed he was called upon as a physician to express the general inadequacy on the part of that branch of the profession to deal with the subject of intestinal obstruction. The function of the physician appeared to him, as has been said before, to come in very early in the case. He must admit that the question of diagnosis is a matter of very great difficulty, where in the case of physiological obstruction there is an absence of indication of local pain or a fever or anything like a bloody discharge from the bowel. Perhaps he may be thought to be a little cowardly, under such circumstances, if he should be inclined to adopt the views of the first speaker rather than of the second, and claim a little time. Sir Wm. MacCormack would, he thought, bear him out in some of his remarks. In a good many of these cases he has operated with the greatest care, but the operation has been performed too late. But in cases in which things seemed most favorable in regard to time, and in which the operation was done with the greatest care and most perfect surgical completeness, it has been as satisfactory in its results as one might have hoped.
